techniques is given in Section “Contacting techniques for DNA and RNA.” The outcome of the simulations and measurements of charge transport in DNA lead nowadays to a good understanding of the electronic nature of the DNA strands. An overview on these results is given in section “Electrical properties of single DNA and RNA molecules.”

Conductance in organic molecules

Concepts for describing charge transport along DNA and RNA are not so different from concepts describing transport of charges in organic molecules. It is therefore constructive to first have a look at these general concepts before discussing special differences arising from the structure of RNA and DNA. The general idea of a charge transport experiment through a single DNA molecule is shown in Fig. 1A. A DNA molecule is connected via anchoring groups to two atomically sharp Au tips. Charge transport in organic molecules is typically measured on short length-scales, that is, Å up to few nm. At these length-scales, tunneling processes dominate, which can be described either by vacuum tunneling (Simmons, 1963) or by resonant tunneling through molecular orbitals, which can be aligned with Fermi energy E_F of the electrodes (Scott and Natelson, 2010) or offset by a certain energy ε_0 (Zotti et al., 2010). Longer molecules on the order of few nm to tens of nm exhibit a transition from tunneling to hopping behavior, which changes the length dependence of the conductance (Moreno-Garcia et al., 2013).

In case of simple tunneling, the tunnel current between two closely spaced electrodes depends linearly on the applied voltage and exponentially on the distance between the electrodes. The current density can be thus approximated by (Wang et al., 2003)

$$J \approx \left(\frac{(2m\Phi_B)^{1/2} e^2 \alpha}{h^2 d} \right) V \exp \left[- \frac{2(2m)^{1/2}}{\hbar} \alpha (\Phi_B)^{1/2} d \right]. \quad (1)$$

Fig. 1 Model of charge transport in molecular junctions (A) Sketch of metallic electrodes connected to DNA molecule (not to scale). (B) Energy diagram for the SLM. Electrons in the metallic electrodes on the left and right fill the available energy states according to Fermi statistics. The molecular state in the center is positioned at an energy ε_0 away from Fermi energy. The exact value of ε_0 depends on the molecular orbitals (highest occupied molecular orbital, HOMO, or lowest unoccupied molecular orbital, LUMO) and the charge transfer between the electrodes and the molecular orbitals. Whether charge transport is dominated by holes (HOMO-like) or electrons (LUMO-like) depends on the nature of the resonance closest to E_F . (C) I - V -curve measured using the mechanically controllable break junction technique (see Section “Break junctions”) and fit to the SLM (red).

Here, m is the (reduced) mass of the electron, h and $\hbar$ are the Planck and reduced Planck constants, respectively, d is the distance between the electrodes, and Φ_B is the height of the tunneling barrier. The factor α accounts for deviations from the perfect rectangular shape of the barrier; it is 1 for a perfect rectangular barrier, otherwise less than unity. Some of the parameters in Eq. (1) depend on the exact shape of the contacts or the tunneling barrier in between. Since it is impossible to characterize the molecular junction on the atomic scale, comparisons of fit results with numerical simulations need to be evaluated in order to determine the fit parameters.

When increasing the bias voltage across the junction, the effective shape of the barrier is affected by the voltage drop. In this situation, approximations leading to Eq. (1) are no longer valid. In this regime, the current density is given by (Wang et al., 2003)

$$J \approx \left(\frac{4}{\pi^2 \hbar d^2} \right) \left\{ \left(\Phi_B - \frac{eV}{2} \right) \times \exp \left[- \frac{2(2m)^{1/2}}{\hbar} \alpha \left(\Phi_B - \frac{eV}{2} \right)^{1/2} d \right] \right\}. \quad (2)$$

The transition between these two regimes can be identified when plotting $\ln(I/V^2)$ vs. $1/V$. This graph shows a clear minimum at the position at which the transition between both regimes happen. Assuming that at this position the energy of the charge carriers is larger than the height of the tunnel barrier, this minimum occurs at the voltage corresponding to the height of the barrier Φ_B (Huisman et al., 2009).

For conjugated molecules with a large conductance, a different view may be more appropriate (Fig. 1B). In this regime, one can assume that charge transport is mostly taking place in the delocalized orbitals of the molecule rather than by tunneling through vacuum. Transmission through the molecule then depends on the nature and number of levels, which are composed of the molecular orbitals. The contribution of these levels depends on their coupling to the electronic states in the electrodes at E_F . If the transmission through the molecule can be approximated by one single resonance with Lorentzian shape, the transmission through the molecular states can be approximated by (Zotti et al., 2010):

$$T(E, V) = \frac{4\Gamma_L\Gamma_R}{[E - E_0(V)]^2 + [\Gamma_L + \Gamma_R]^2} \quad (3)$$

Based on this assumption, which is also referred to as single-level model (SLM), the current through the molecular junction can be calculated via:

$$I(V) = \frac{2e}{h} \int_{-\infty}^{\infty} T(E, V) \left[f\left(E - \frac{eV}{2}\right) - f\left(E + \frac{eV}{2}\right) \right] dE \quad (4)$$

Eq. (4) can be used to fit the measured current–voltage (I – V) curve (Fig. 1C) and extract the single-level model parameters (SLM parameters ϵ_0 and Γ). This gives information on the energetic position of the channel transporting charge along the molecule and the electronic coupling to the electrodes.

For longer molecules, the assumption that a single state on the molecule transports the charge does not hold any more. In this situation, one needs to assume that a series of localized charge states exist along the molecule. Transport between these states occurs by hopping with an amplitude proportional to the hopping matrix element $t_{i,j}$, where i, j refer to the hopping sites ($1 \leq i, j \leq N$ for N hopping sites). When measuring the conductance of molecular junctions as a function of the length of the contacted molecule, one therefore finds a transition from the tunnelling behavior described by Eq. (1) or (4) to a hopping conductance (Choi et al., 2010).

Although these conductance models have been derived for organic molecules in general, they are still valid for contacts to single DNA or RNA molecules. The situation changes once ensembles of molecules are contacted because in this case, collective effects become more dominant. We therefore concentrate mostly on the behavior in single DNA doublestrand molecules. Some experiments at room temperature show transport along the molecules which resembles the SLM picture mentioned above. Other experiments show that transport at low temperatures may be along the backbone of the DNA because the base dependence found at room temperatures could not be found at low temperatures. All these experiments confirm the initial finding that the environment of the DNA has a major influence on the charge transport. We will therefore first discuss experimental techniques for contacting single DNA and RNA strands because the techniques determine the environment. Based on these techniques, we will then describe experimental results found on different molecules and discuss them in the framework of the techniques presented in this section.

Contacting techniques for DNA and RNA

Contacting single molecules can be achieved using a large variety of techniques. The main challenge in such experiments is given by the small size of the molecules, which requires structuring of the electrodes on sizes below 5 nm. No lithographic process is available for the creation of electrodes on such small length scales. Therefore additional steps need to be taken for including the molecules in such nanojunctions. The length of a single DNA strand can be much longer than typical organic molecules, sometimes exceeding even 100 nm. Therefore also direct contacting methods have been used for creating contacts, as well. Charge transport on such extended lengths is, however, suppressed in most cases.

Famous first experiments have been performed on DNA strands with fixed electrodes at lengths in the micrometer range (Fink and Schönenberger, 1999; Porath et al., 2000; Braun et al., 1998; Kasumov et al., 2001). It soon turned out that apart from the

presence of the DNA itself, the conformation of the DNA and the exact conditions of the environment determine the conductance of the DNA nanojunctions (Endres et al., 2004). Several methods have been developed which allow the contacting of DNA single and double strands under more controllable conditions, and therefore the controlled characterization of the electrical properties of these structures.

Conducting atomic force microscopy

Conducting atomic force microscopy (c-AFM) offers the possibility to image surfaces on the nanoscale and at the same time measure their electrical properties. This method has first been used for conjugated organic molecules which were embedded in a matrix of nonconjugated, electrically insulating molecules (Cui et al., 2001). A monolayer of a mixture of these molecules was self-assembled on top of an atomically flat Au layer (substrate). For specifically contacting the conducting molecules with the c-AFM tip, these molecules were functionalized with thiol groups, to which Au nanoparticles could bind. When contacting these nanoparticles with the tip of the c-AFM, a metal–molecule–metal contact is formed between tip/nanoparticle on the one side and the conducting substrate on the other side. It is shown in Fig. 2A how the connection is achieved in case of DNA strands. The coupling to the Au nanoparticles could be achieved by binding a DNA strand to the particle, which is complementary to the strands, which are bound to the substrate (Cohen et al., 2005). Charge transport can then be measured through a single double-stranded DNA formed by this combination inside a matrix of single-stranded DNA.

The c-AFM technique can be used for the direct transport measurement along DNA molecules as well. The molecules are deposited on an insulating surface, for example, SiO_2 . One end of the molecule is covered with metal creating one of the two contacts. The other contact is given by the tip of the c-AFM, which is used to scan and image the molecules and then to electrically contact them along the molecule. The setup allows for recording I - V curves at various points of the molecule (Stern et al., 2018; Livshits et al., 2014). This technique was used for metallized strands as well as for bare DNA on the surface.

Fig. 2 Different contacting techniques: (A) Conductive atomic force microscopy (c-AFM). The AFM cantilever with a conductive tip is brought into contact with a metal particle in order to measure current through the metal particle and the ds-DNA to the metallic substrate. (B) STM breakjunction technique. The metallic STM tip is connected to a ds-DNA via thiol bonds, the DNA is connected to the substrate via a thiol group at the other end of the strand. Contacts are repeatedly formed by pushing the tip into the substrate which is covered by molecules and retracting it again. During this procedure, the current through the molecule is measured at a fixed bias voltage. (C) Mechanically controllable break junction (MCBJ). An SEM image of a metallic, underetched nanobridge is shown. The bridge is placed on a flexible substrate and, upon bending, stretched until the contact between the metal atoms is lost. A ds-DNA can be connected to both tips (sketch above), the conductance and I - V -characteristics can be measured in this configuration. (D) Electrodes with fixed distance. DNA molecule between two metallic CNTs, which serve as contacts. The DNA is suspended in the gap between the CNTs, therefore interaction with the substrate is minimized. Scale bar 30 nm. Break junctions

Systematic studies of the influence of the primary structure of DNA on the conductance of DNA nanojunctions need statistical information based on a large number of measurements. Using the scanning tunneling microscope (STM) on metallic substrates with self-assembled monolayers of ds-DNA, contacts to the DNA can be formed repeatedly by pushing the tip into the substrate and pulling it back while measuring the conductance as a function of the distance d between the STM tip and the substrate (STM breakjunction technique). In this measurement, G decreases exponentially with increasing d , unless a conducting molecule is attached between tip and substrate and charge transport is observed along the molecule. In this case, G exhibits a plateau with a length roughly corresponding to the length of the molecule. Fig. 2B shows the situation in which the ds-DNA is completely stretched between the substrate and the tip. This situation would correspond to the final points in the plateau, before the DNA loses contact on one end and the resistance drops exponentially to zero upon further stretching. The plateau causes an accumulation of data points corresponding to the value of G on the plateau, which can be identified when the histograms of the occurrence of the conductance values are evaluated (Venkataraman et al., 2006). This method is well-known from the identification of single-atom contacts in metallic junctions (Scheer et al., 1998). The conductance of a molecular junction, however, is orders of magnitude lower than that of a metallic junction, indicating the off-resonant nature of the charge transport through the molecules. This method was successfully demonstrated for characterization of the dependence of the conductance of DNA strands on their base sequence (Xu et al., 2004). Fig. 2C shows an SEM image of the metallic bridge, which is used to contact the molecules. The main difference of this technique compared to STM breakjunctions lies in the slow speed at which the electrodes are moved apart, which results in lower statistics but larger stability for single measurements. It is therefore easier to record stable I - V curves using the mechanically controllable break junctions (MCBJs) as the STM breakjunctions. Using MCBJs, ds-DNA and G-quadruplex structures could be contacted using two tips with adjustable distance (Liu et al., 2013, 2010).

Electrodes at fixed distances

The pairing of base pairs was successfully used for integration of ds-DNA in between electrode with fixed distance. The main advantage of this approach is given by the fact that the difference between measurements on nonconducting ss-DNA and conducting ds-DNA can be directly seen using the same contacts. Examples for this approach are measurements using metal contacts and metallic carbon nanotubes (CNTs) (Guo et al., 2008). Fig. 2D shows an AFM image of a junction, in which a ds-DNA is connected to a gap in two suspended CNTs and can be clearly imaged. This approach can be further perfected by binding Au nanoparticles to both ends of the DNA molecule. This can be achieved in a similar way as was described for the c-AFM technique. The nanoparticles are bound to ss-DNA with a sequence, which is complementary to the end of the DNA to be measured. These nanoparticles are bound to both ends of the molecules, which can then be deposited on an insulating substrate. The main advantage of this approach is that the Au nanoparticles can be identified and contacted using electron beam lithography (Roy et al., 2008; Zhuravel et al., 2020).

Electrical properties of single DNA and RNA molecules

The experimental techniques described above facilitate the controlled measurement of DNA and RNA in a controlled environment. The results depend on the contacting technique, but most of the differences can be attributed to the variations in environmental conditions due to the different contacting methods. We therefore review the experimental results grouped by contacting method and compare the main conclusions with conclusions drawn from theoretical calculations.

The main results of initial characterization measurements based on STM and c-AFM techniques revealed nonlinear s-shaped curves in a resistance range from 100 k Ω to 1 G Ω . Typical examples of such curves are shown in Fig. 3A. The nonlinearity of the curve can be explained with transport along the ds-DNA in the presence of a characteristic energy gap. Such energy gaps are characteristic for semiconducting and organic micro- and nanostructures. One can therefore conclude from these experimental results that charge transport along ds-DNA occurs along delocalized orbitals, which are formed by the structure of the molecule. ss-DNA does not exhibit any measurable conductance and is therefore considered to be insulating (Cohen et al., 2005). This indicates that the secondary and the tertiary structures of DNA are essential for the conductance of single DNA strands. The influence of the base sequence on charge transport can be seen when comparing sequences containing different amounts of G-C and A-T pairs. Using the STM break-junction method, it was experimentally shown that molecules consisting of G-C pairs exclusively (pG-pC DNA) are conducting with a resistance in the range of a few M Ω while molecules only built from A-T pairs (pA-pT DNA) have much higher resistance (Xu et al., 2004). In Fig. 3B conductance histograms for three different ds-DNA strands are shown. The histograms exhibit clear maxima at conductance values corresponding to transport through single molecules that are attached to the substrate and the tip, respectively, on both ends. The conductance decreases when A-T pairs are introduced into pG-pC molecules. Studies of the length dependence of charge transport along ds-DNA have shown a transition between tunneling at short distances and hopping at longer distances for strands containing A-T pairs, which does not appear for pure G-C strands up to 16 bases (Li et al., 2016). This transition can be seen in Fig. 3D, where the conductance of ds-DNA is plotted logarithmically as a function of the number of base pairs. A-T pairs inside otherwise pure G-C structures can therefore be regarded as tunnel barriers in a conducting channel.

Fig. 3 Experimental results on charge transport through DNA molecules: (A) Nonlinear curve measured on ds-DNA using the c-AFM technique. (B) Histograms from opening curves measured using the STM breakjunction technique for ds-DNA with various base sequences. The lowest lying maximum in the histogram corresponds to junctions with single molecules. The resistance value at this maximum is therefore a measure for the metal-molecule-metal junction. The resistance is lowest for pC-pG wires. (C) Comparison between charge transport through ss-DNA and ds-DNA connected to CNTs (as shown in Fig. 2). (D) Transition between tunnelling and hopping for increasing number of AT base pairs in the ds-DNA. The idea of transport through a single transport channel is further supported by measurements of G-C rich DNA fragments in MCBJ setups. At a fixed electrode distance, I - V curves were measured and compared to predictions by the SLM. In situations, in which a single ds-DNA strand binds to both electrodes, the transport can be fitted well to curves calculated based on (4). In analogy to measurements on single, organic molecules (Zotti et al., 2010), this can be seen as a hint that the base sequence creates a path for resonant tunneling of charges along the DNA. Measurements at varying electrode distances show a transition from pure tunneling at short distances to symmetric coupling with resonant tunneling at distances comparable to the DNA fragments to an asymmetric coupling at even larger distances. Further stretching of the junctions finally leads to a loss of conductance because the contact to the molecules is broken. This behavior can be modeled by assuming that first the contact between molecule and electrode is broken on one end, then the junction is stretched so far that the total tunnel current vanishes. Such a stretching behavior is modified when G-quadruplex structures are contacted. In these structures, the planes constituted by the G-bases can slide with respect to each other without losing the electronic coupling (Liu et al., 2010).

Theoretically, it has been confirmed that fluctuations of the molecular structure, which can be imposed by the presence of a solvent modify the coupling between the bases substantially (Gutierrez et al., 2009). Fig. 4A shows in a model presentation of this idea how the coupling of the sites to the phonon bath leads to additional energy states in the charging gap. Molecular dynamics simulations combined with quantum-chemical calculations and a model Hamiltonian approach were used to evaluate the contribution of different bases to the charge transport across the molecules. It turns out that transmission through pG-pC structures leads to a transmission close to E_F of Au while transmission through pA-pT structures occurs at considerably lower energies (see Fig. 4B). For extended structures, that is, long molecules, one can assume that transport between G bases occurs via hopping between the bases while parts with A-T pairs act as tunnel barriers. Fig. 4C depicts this transport behavior for pure poly G-C wires and poly G-C with partly A-T regions, respectively. The dominating effects on the transport behavior, however, are given by dynamical disorder, which is mainly caused by fluctuations of the DNA structure. Especially in liquid environment, which is needed to stabilize the double-helix structure of DNA, these fluctuations dominate the transport behavior. Fig. 4D shows simulated curves for pG-pC and pA-pT DNAs in a environment with fluctuations. The current is similar for both structures, indicating that the role of fluctuations in this regime is more dominant than the role of the base pair configuration.

Fig. 4 Theory of charge transport in DNA: (A) Contact to the phonon bath creates midgap states which dominate charge transport at E_F . (B) Calculated electronic coupling between the different base pairs, showing that GG coupling occurs at the lowest energy and gives rise to the most efficient charge transport path. (C) Sketch of the difference between hopping along pG-pC wires and AT pairs, which act as tunnel barriers Li et al. (2016). (D) Comparison between calculated transport through pG-pC and pA-pT molecules. The overall current levels are similar, when fluctuations are taken into account. The role of fluctuations could be confirmed by comparing the behavior of pure RNA double strands with DNA:RNA hybrids in STM-breakjunction experiments (Chandra et al., 2022). Pure RNA double strands show similar conductance values as ds-DNA with similar base sequence. This confirms the idea that charge transport along these strands occurs mostly by hopping between different bases and is therefore determined by the intrastrand interactions between the bases. The variation of the conductance values is larger in case of RNA compared to DNA:RNA. MD simulations confirm that the origin of this phenomenon is most likely the different mechanical behavior of the two species.

The large conductance along G-bases can also be seen in other structures, for example, the so-called G-quadruplex structures. In MCBJ-breakjunction experiments, the resistance of the G-quadruplexes, which were contacted between two Au electrodes, as a function of distance between the electrodes could be recorded (Liu et al., 2010). Long plateaus at resistance values in between 100 k Ω and 10 M Ω indicate that the G-quadruplex can be stretched over several nm without changing the conductance of the junction. This can be explained by the overlap between G-bases in different layers of the quadruplex. It was found, however, that for G-quadruplexes lying on a conducting surface the energy gap, through which charge transport occurs, strongly depends on the position and therefore most likely on the geometric constraints of the molecule (Shapir et al., 2010). This was demonstrated by measuring scanning tunneling spectroscopy curves along G-quadruplex strands and categorizing the resulting curves in order to identify relevant energy states.

Using dimers consisting of ds-DNA and covalently bound Au nanoparticles, charge transport in long, freestanding, and dried ds-DNA could be measured (Zhuravel et al., 2020). In the absence of solvent effects, the measurements could be taken at various temperatures down to 5 K. In contrast to measurements in liquid environment, the transport shows no strong dependence on the base sequences of the DNA. It can be suppressed, however, by introducing defects (“nicks”) in the strands. A single nick in one strand does not affect the current value at finite voltages, but if both strands are nicked at least once, the current is suppressed. These two findings in combination with the temperature dependence of the charge transport indicate that in this configuration the majority of the charge transport occurs by hopping along the backbone. This result is confirmed by ab initio electronic structure calculations and transport calculations.

Nanopores

Nanopores in electrically insulating membranes can be used for the detection of ionic currents between the two sides of the membranes (Xue et al., 2020). These ionic currents are influenced by the presence of a molecule, such as DNA or a protein. Therefore, changes in the amplitude of the ionic current give information on the electrical properties of the molecule inside the pore. By designing the pore geometry (length and diameter) properly, the resolution of this measurement technique can be brought to a stage at which single DNA bases can be detected (Manrao et al., 2012). In such experiments, the DNA is typically unzipped and guided through the pore at a speed which is low enough to distinguish the changes in ionic current above noise level. Recent improvements of this basic principle include fabrication of nanopores in artificial membranes, which improve selectivity and throughput (Xue et al., 2020). Nanopores have thus been a standard tool for DNA sequencing even on the commercial level (Mauger et al., 2020). The detection principle, as mentioned before, relies on the detection of ionic currents in the solution surrounding the DNA molecules and is therefore only weakly linked to the electronic properties of the DNA molecules themselves.

DNA Origami

As shown above, the conductance of double-stranded DNA with pG-pC base sequences indicates delocalized charge transport along the DNA with, however, comparably low transmission. The resulting resistance in the $M\Omega$ range is far too large for charge transport over long ranges. Therefore, electronic structures based on pure DNA molecules will unlikely be able to be used for the construction of large electronic circuits. The DNA origami method (Rothemund, 2006), however, allows the formation of arbitrary shapes on the nanoscale, which can be functionalized with conducting particles. Using this method, metallic nanostructures can be created, which can be used as wires for charge transport across lengths exceeding 100 nm (Bayrak et al., 2018; Aryal et al., 2018). More complex structures leading to junctions or nanogaps can be developed by implementing T-crossings and links between the different building blocks, for example, nanomolds which can be filled with semiconducting or metallic material (Ye et al., 2021). The deterministic self-assembly of the Origami structures then allows to include ds-DNA into these nanogaps with high precision. Therefore, this technique may ultimately lead to DNA electronics integrated in larger circuits, which are created using self-assembly. Apart from this, the conformational changes possible in DNA Origamis allow for reconfigurations in liquid environments. These dynamic changes in the position of conducting nanoparticles can be used for changing the optical properties of the assemblies and thus open vast possibilities in this area. For electronic readout, however, the liquid environment is typically detrimental. Therefore such applications are not within the scope of this article.

Conclusion

Charge transport along DNA and RNA molecules depends on the one hand on the structure of the DNA, for example, the base sequence and the conformation of the molecule, and on the other hand on the environment, which is mostly determined by the contacting techniques. Due to the development of reliable contacting techniques for single molecules, the understanding of charge transport in DNA and RNA could be advanced during the past two decades. Based on this experimental evidence one can conclude that charge transport at room temperature occurs by tunneling along the bases, with a coupling energy between the bases depending on the base. Fluctuations create states below the coupling energy similar to midgap states in semiconductors. At low temperatures, charge transport has been shown to be carried by the backbone of the molecule and is therefore independent of the base sequence. In all cases, the resistance of the DNA molecules is most likely too large for direct use in electronic applications. Therefore, concepts were developed to use self-organized nanostructures based on DNA, for example DNA Origamis. With these nanostructures, complex circuits can be built and bring DNA nanoelectronics closer to application.

Introduction

Cells are controlled by the action of molecules upon molecules. Receptor proteins in the outer cell membrane sense the environment and may subsequently induce changes in the states of specific proteins inside the cell. These proteins then interact again and convey the signal further to other proteins and so forth, until some appropriate action is taken. The final results of such signaling may be a transcription regulation, thereby making more of some kinds of proteins.

The reader is reminded that proteins are produced from DNA through a two-step process, where first the DNA code is transcribed into mRNA by an RNA polymerase, and subsequently, the mRNA is translated into a protein by a ribosome. This is illustrated in Figure 1. The simplest way that one protein regulates the production rate of another protein is illustrated in Figure 2. The regulated protein may in turn regulate other proteins, and thereby be part of the transcription regulatory network. Regulatory genetic networks are essential for epigenetics and thus multicellular life, but are not essential for life. In fact, there exist prokaryotes with nearly no genetic regulation.

An interesting overall observation dealing with the architecture of genetic regulatory networks is that the fraction of proteins that regulate other proteins N_{reg}/N increases with total number of proteins N . In other words, the relative size of the bureaucracy increases with system size. In fact for prokaryotes, the fraction of regulators increases linearly with the system size, reaching $\sim 10\%$ for the prokaryote *Pseudomonas auriginosa* with its ~ 6000 genes. If a living cell could be understood as an essential core plus a number of modules (genes regulated together), each, for example, associated to respond to a corresponding external situation, then the fraction of regulators would be independent of the number of genes N . The fact that N_{reg}/N grows linearly with N indicates that each added gene or module should be regulated with respect to all other gene modules. Thus, already prokaryotic organisms show features of a highly integrated computational machine. Networks are indeed important, from the smallest hubs with feedback to the whole integrated circuitry.

Topology of Genetic Regulatory Networks

In Figure 3, the known regulatory network for the single-celled eukaryote, the yeast *Saccharomyces cerevisiae* is shown. One feature of regulatory networks is the wide distribution of directed arrows from individual proteins. There are many proteins which control only few other proteins, but there also exist some proteins which control the expression level of many other proteins. In fact, the distribution of proteins with a given number of neighbors (connectivity) K may (very crudely) be approximated by a power law

$$N(K) \propto 1/K^\gamma \quad [1]$$

with exponent $\gamma \sim 1.5 \pm 0.5$ for the “out-degree” distribution of transcription regulators (see Figure 4). It is also to be noticed that the distribution of the number of proteins in which a given protein regulates, the “out-degree” differs from the narrower distribution of “in-degrees.” Overall however, both of these distributions are broad, and one would like to develop an intuition to find possible reasons why life organizes its regulation in this way.

One aspect of a wide distribution of connectivity in signaling networks is the possible amplification of signals in the network. Thus on an average, a signal entering a node could be transmitted to a number of other nodes given by the amplification factor:

$$\begin{aligned} \mathcal{A} &= \frac{\langle K_{\text{in}} K_{\text{out}} (\text{given } K_{\text{in}}) \rangle}{\langle K_{\text{in}} \rangle} \\ &= \frac{\langle K_{\text{in}} K_{\text{out}} \rangle}{\langle K_{\text{in}} \rangle} \end{aligned} \quad [2]$$

the last equality implies that the output connectivity is independent of the input connectivity. The above formula follows from following a signal that enters a node with probability proportional to K_{in} , and leaves along any of the K_{out} links. The equation is thus the average amplification factor in a randomly wired directed network. When $\mathcal{A} > 1$, signals tend to be exponentially amplified and thus, most signals will influence signaling over the entire network. For networks with degree distribution which is a power law, $\mathcal{A}$

Figure 1 RNA polymerase (RNAP) moves along the DNA while transcribing it into an mRNA string. This mRNA is subsequently translated into a protein by a ribosome, here shown in black. The same mRNA may easily be translated into several proteins.

Figure 2 On left panel an example of a transcription factor is shown, the protein CAP that binds to a piece of DNA. On right panel is illustrated respective positive and negative regulation by a transcription factor (TF) on a protein shown as a green filled circle. The TF is a protein that binds to a region on the DNA called an operator (dark region on the DNA). The positive regulation is through a binding between the TF and the RNAP, that increases the chance that RNAP binds to the promoter that is shown as a medium dark region on the DNA strand. Negative regulation occurs when the operator is placed such that the bound TF prevents the RNAP from binding to the promoter. On the rightmost panels is shown how one typically draws the elementary regulation as an arrow in a regulatory network.

typically depends on the most highly connected node. Thus, highly connected nodes will be effective in transmitting a signal very fast to a substantial part of the whole system. This has obvious advantages, and may be one of the reasons why one also observes very highly connected nodes in both genetic and other signaling networks in living cells.

Power-law networks have also been proposed to be due to statistical processes, with little regard to functionality. One very widespread suggestion is the preferential attachment idea, that uses the fact that, if a network is growing by a mechanism where each new node is attached to nodes selected as being in the ends of already existing links in the network, then one obtains a steadily growing scale-free network. Another suggestion is the observation that even a nongrowing network can develop into a steady-state attractor with a scale-free degree distribution, if one assumes that a major element in the network rewiring dynamics is merging of old vertices and creation of new vertices. In the perspective of signaling networks, the latter model represents an on-going attempt to minimize the length of signaling pathways, competing with an on-going pressure to increase the protein diversity. In any case, traces of the actual evolution of networks can be quantified using the rather frequent gene duplication and associated protein homologs that one finds in any presently living organism. The overall lesson of such studies is that the genome of any organism is dynamic, and that reorganizations indeed are possible if they are functionally desirable.

The real reason for the observed broad distribution of edge degrees in biological networks should probably be seen in the perspective of where especially the highly-connected nodes sit in the network. To analyze this, a discussion on how to analyze network topologies beyond the degree distribution is taken up now. The key idea is to generate a random network, and then to compare this with the real network.

As was pointed out in the general context of complex scale-free networks, a broad distribution of degrees indicates that the degree itself is an important individual characteristic of a node and as such, it should be preserved in the randomized null-model network. In addition to degrees, one may choose to preserve some other low-level topological properties of the network in question. Any measurable topological quantity, such as, the total number of edges connecting pairs of nodes with given degrees, the number of loops of a certain type, the number and sizes of components, the diameter of the network, can then be measured in the real complex network and separately in its randomized version. One then concentrates only on those topological properties of the real network that significantly deviate from their null-model counterpart.

Figure 3 Presently known transcription regulations in yeast (*Saccharomyces cerevisiae*), with green arrows indicating positive regulation (activation) and red arrows indicating repression.

Figure 4 Statistics of regulation in the yeast *Saccharomyces cerevisiae*. (Data from Proteome.)

Figure 5 One step of the local rewiring algorithm. A pair of directed edges $A \rightarrow B$ and $C \rightarrow D$. The two edges then switch connections in such a way that A becomes linked to D , while C to B , provided that none of these edges already exist in the network, in which case the move is aborted and a new pair of edges is selected. An independent random network is obtained when this is repeated a large number of times, exceeding the total number of edges in the system. This algorithm conserves both the in- and out-connectivity of each individual node. (Reproduced from Maslov S and Sneppen K (2002) Specificity and stability in topology of protein networks. *Science* 296: 910–913; American Association for the Advancement of Science.)

An algorithm giving rise to a random network with the same set of individual node degrees, as in a given complex network, was proposed by Maslov S and Sneppen K in 2002. It consists of multiple repetitions of the following simple switch move (elementary rewiring step) illustrated in Figure 5: “Randomly select a pair of edges $A \rightarrow B$ and $C \rightarrow D$ and rewire them in such a way that A becomes connected to D , while C to B .”

To prevent the appearance of multiple edges connecting the same pair of nodes, the rewiring step is aborted and a new pair of edges is selected if one or two of the new edges already exist in the network. A repeated application of the above rewiring step leads to a randomized version of the original network. The set of MATLAB programs generating such a randomized version of any complex network can be downloaded from the internet.

Sometimes it is desirable that the null-model random network in addition to degrees of nodes, conserves some other topological quantity of the real network. In this case, one could supplement the random rewiring algorithm described above with the Metropolis acceptance/rejection criterion.

The “correlation profile” of any large complex network quantifies correlations between degrees of its neighboring nodes. The topological property of the network giving rise to its correlation profile is the number of edges $N(K_0, K_1)$ connecting pairs of nodes with degrees K_0 and K_1 . To find out if in a given complex network the degrees of interacting nodes are correlated, $N(K_0, K_1)$ should be compared to its value $N_r(K_0, K_1) \pm \delta N_r(K_0, K_1)$ in a randomized network, generated by the edge rewiring algorithm. When normalized by the total number of edges E , $N(K_0, K_1)$ defines the joint probability distribution $P(K_0, K_1) = N(K_0, K_1)/E$ of degrees of interacting nodes. Any correlations would manifest themselves as systematic deviations of the ratio

$$R(K_0, K_1) = P(K_0, K_1)/P_r(K_0, K_1) \quad [3]$$

away from 1. The correlation profile for the yeast regulatory network is shown in Figure 6. The statistical significance of such deviations can, in principle, be quantified by their Z-score

$$Z(K_0, K_1) = (P(K_0, K_1) - P_r(K_0, K_1))/\sigma_r(K_0, K_1) \quad [4]$$

where $\sigma_r(K_0, K_1) = \Delta N_r(K_0, K_1)/N$ is the standard deviation of $P_r(K_0, K_1)$ in an ensemble of randomized networks.

The result of the above analysis is that there is a significant suppression of links between hubs, both for regulatory networks analyzed in Figure 6 and also for the protein networks measured in large-scale two-hybrid experiments on yeast. Similarly, by

Figure 6 Correlation profile showing correlation between connected proteins in the regulatory network of yeast, quantified in terms of Z scores. The single output module is reflected in the abundance of high K_{out} controlling single K_{in} proteins. The dense overlapping regulons correspond to the abundance of connections between $K_{out} \sim 10$ and $K_{in} \sim 3$ proteins. Finally, the suppression of connections between highly connected proteins show that these tend to be on the periphery of the network. (Maslov S and Sneppen K (2002) Specificity and stability in topology of protein networks. *Science* 296: 910–913.)

Figure 7 Genetic control motifs which are found to be over represented in regulatory networks of both *E. coli* and yeast. (Milo R, Shenn-Orr S, Itzkovitz S, Kashtan N, and Chklovskii D (2002) Network motifs: simple building blocks of complex networks. *Science* 298: 824–827.)

defining higher-order occurrences of various local patterns of control, Shen-Orr and co-workers suggested some frequent motifs of gene control in 2002, as illustrated in Figure 7.

Finally, it may be mentioned that the tendency of highly connected proteins to be at the periphery of regulatory networks in itself teaches one something about the origin of broad connectivity distributions. To see this, one could consider the fact that a protein is a fairly simple unit, that presumably gives essentially the same information to each of its downstream targets. Thus, the feature that a hub protein sits on the periphery of the network and does not link to other hub proteins, presumably reflects a one-hub-one-function structure. As a corollary of this, one may suspect that the broad distribution of molecular networks is not an intrinsic property of the network, but rather reflects the broad distribution of external requirements that the surroundings of an organism puts on it. Some functions simply require many proteins, whereas many functions require only a few proteins. This scenario is also supported by the observation that there is essentially no correlation between connectivity of a regulatory protein and its importance measured by its chance to be essential in knock-out experiments. If highly connected proteins were involved in many functions, their likelihood of being essential would grow linearly with their connectivity. This is not the case, for the yeast transcription network: the chance that a transcription factor is lethal is independent of how many proteins it regulates!

To summarize the topological properties of regulatory and signaling networks, the broad connectivity distributions may very well reflect the widely different needs associated to widely different functions that a living cell needs to cope with as it changes its environment.

Combinatorics in Genetic Networks, and an Evolution Model

In addition to the topological properties, the regulation of genes also have a combinatorial part. This means that the regulation of a given gene may depend on the combination of the concentration of its regulators. An inspiring way to model such a combinatorial regulation was proposed already in 1969 by S Kauffman. In this very simplified approach, each gene was assigned a binary number, 0 or 1, that counts whether the gene was off or on. Each gene i was assumed to be on or off depending on some logical function of the state of the gene that regulated it. A very simple version of this Boolean rule would be the threshold network where the state of the gene i at time t is given by

$$\sigma(i, t) = \Theta\left(\sum A_{ij}\sigma(j, t-1)\right) \quad [5]$$

where $\Theta(x)$ is zero for $x < 0$ and $=1$ otherwise. The A_{ij} is nonzero for genes j that regulate gene i . A_{ij} is positive for activation, and negative for repression. For a large regulatory network, the above update defines a cellular automata in a geometry defined by the connectivity matrix. Starting in an arbitrary initial condition, the system will move through a sequence of states that at some point is bound to repeat itself. This is because the state space is finite and the update deterministic. Thus, much effort has been used to characterize the behavior of these attractors as a function of the connectivity pattern of the system. One simple result is that the system undergoes a percolation phase transition when the average connectivity is increased beyond a critical out-connectivity $\langle K_{out} \rangle \sim 2$. Above this transition, the attractors become very long (exponentially growing with system size) and the behavior is called chaotic.

The Boolean paradigm allows for modeling large-scale expression patterns of idealized regulatory networks. Thus, it also allows one to address how long-time evolution of rewiring and changes of combinatorial rules may constrain the evolution of such networks. In this regard, it is especially interesting to consider robustness as an evolutionary principle. One way to implement this is to "Evolve a new network from an old network by accepting rewiring mutations with a probability determined by the expression overlap."

This minimal-constraint scenario has no outside fitness imposed. Also, it ignores competition between networks, as it only compares a network with its predecessor. However, the model naturally selects networks which have a high overlap with neighbor mutant networks. This feature is associated to robustness, defined as the requirement that not only should the present network

work, but also mutations of the networks should work. In terms of network topology, this means a change in the wiring $\{A_{ij}\} \rightarrow \{A'_{ij}\}$ that takes place on a much slower timescale than the $\{\sigma_j\}$ updating using the Boolean dynamics itself.

The system that is evolved is the set of couplings A_{ij} in a single network. One evolutionary time-step of the network is:

1. Create a daughter network by (a) adding, (b) removing, or (c) adding and removing a weight in the coupling matrix A_{ij} at random, each option occurring with probability $p=1/3$. This means turning an $A_{ij}=0$ to a randomly chosen ± 1 or vice versa.
2. Select a random input state $\{\sigma_i\}$. Iterate simultaneously both the mother and the daughter system from this state until they either have reached and completed the same attractor cycle, or until a time where $\{\sigma_i\}$ differs between the two networks. In case their dynamics is identical, then replace the mother with the daughter network. In case their dynamics differs, keep the mother network.

The result of this type of modeling is an intermittent evolutionary pattern: occasionally the evolved network is trapped in states with few evolution paths away from it; sometimes it is, instead, in highly active regions of “network space,” thus allowing fast readjustments of genome architecture. More important, the obtained network exhibits a less chaotic behavior than random ones. The computational structure thus emerging has a simplicity of form consistent with that obtained with real molecular networks by placing highly connected nodes on the periphery of the network. In the Boolean model networks explored here, the attractors for the networks are shorter, and there are more frozen regulators in a random network at the same average connectivity.

The Cell Membrane as an Equivalent Circuitry of Parallel Ion Channels with Variable Conductance: An Explanation for Complex Changes of Membrane Voltage	695
Further Reading	698

All living cells are surrounded by lipid membranes that are impermeable to ions and any large or charged molecules. With this, lipid barrier cells are able to separate a well-defined ionic environment inside the cell, the cytoplasm, from the extra cellular solution and also from internal compartments. The purpose of internal compartmentation is that biochemical reactions with different ionic requirements can occur simultaneously without interfering. A schematic representation of the main cellular compartments of a typical animal cell is illustrated in [Figure 1](#). The maintenance of these compartments and the integrity of the membranes is an absolute requirement for cellular life.

As much as the separation of compartments by membranes is important for cell function, a tightly controlled and selective communication between the individual compartments is required. Such a communication cannot occur via simple diffusion across the lipid membrane, because this process is much too slow. Cells have therefore evolved specific transport proteins, which facilitate the diffusion of ions and solutes through the membrane in a selective and regulated fashion.

Ion channel proteins represent a very efficient mechanism of facilitated diffusion. Due to the architecture of the channel pore (see section “Structure and function of transport proteins”), these transporters allow ions to cross membranes at rates which approach diffusion in water.

Diffusion is a passive process and occurs energetically only downhill. However, cells often have to concentrate ions in different compartments and in order to do this they have to move ions against their concentration gradient (see [Figure 1](#)). To this purpose cells utilize a class of transport proteins, termed pumps, which drive active, energy-consuming transport across the membranes. Active transport of a solute against its concentration gradient is driven by the energy released in the hydrolysis of a high-energy molecule, ATP. The pumps are therefore also called ATPases.

Transport of solutes against their gradient does not necessarily require the presence of a primary active transport system. The movement of solutes can also be coupled to the movement of other molecules down their respective electrochemical gradients (secondary active transport). In this case, the potential energy stored in ionic gradients (by the ATPases) can be utilized to transport other solutes. An example for this type of transporter is the Na^+ /glucose co-transport. The concentration of sodium $[\text{Na}^+]$ is kept low in the cytoplasm by the primary active transport system (the Na^+/K^+ ATPase). The glucose molecules are driven by secondary active transport by a Na^+ /glucose co-transporter.

The best understood transporters to date, in terms of structure and function, are ion channels. This has two reasons. One reason is their key role in important physiological reactions such as nerve activity and muscle contraction. However, more significant for their understanding is their high turnover rate which allows them to be investigated at the single protein level. Two techniques, the planar lipid bilayer and the patch clamp technique, have greatly improved our understanding of ion transport through channels. The main features of the two methods are illustrated in [Figure 2](#). The characteristic of the former approach is that the performance of a channel protein, even those from intracellular membranes, can be measured in a completely artificial system, in which all components such as the composition of the lipids and of the solutions are under the control of the experimenter, while the latter method allows one to measure channels in their native environment.

Both techniques report essentially the same kind of activity from ion channels. [Figure 3](#) illustrates a typical patch clamp recording of single-channel fluctuations in a membrane. The channel fluctuates between an open and a closed state. When it opens, it gives rise to a current, measured in picoampere (pA), with the characteristic open-channel amplitude. A single-channel current of 1 pA as in [Figure 3](#) corresponds to a flow of 6×10^6 ions per second.

In the simplest case, the conductance of an open channel behaves like an Ohmic resistor increasing linearly with the driving force. The slope of the current/voltage relation is a measure of the conductance of a channel. The conductance is characteristic of each individual channel proteins. In the case of potassium channels, they are in the range of picosiemens (pS).

The possibility of measuring and controlling the solution composition on both sides of the membrane allows examining the selectivity of these proteins. If a channel were perfectly selective for only one ion, the measured equilibrium voltage should match that predicted from the Nernst equation. Any other behavior indicates that the channel is either less selective or even, in the extreme case, not selective at all for a given ion. Channels of the latter kind have been described but they are a minority among the physiologically relevant channels, which are in general highly selective. Experiments performed in the way indicated above show,

Figure 1 Concentration of main cations and pH in a typical animal cell and in some selected endo-compartments. O, external solution; C, cytoplasm; ER, endoplasmic reticulum; L, lysosome.

Figure 2 Sketch of main experimental techniques for single-channel recording. Planar lipid bilayer: two chambers (c1, c2) are connected by a small hole. This hole is sealed by a lipid bilayer reflecting a biological membrane. Vesicles (v) containing a channel protein (black dot) are made to fuse with this bilayer. This results in an incorporation of the channel protein into the bilayer. The activity of this channel can be recorded as a current between the two chambers. Patch clamp: A patch clamp pipette is sealed against the membrane of a cell. The current through a channel (here indicated by black dot) can be recorded. With different procedures, the membrane patch underneath the electrode can be isolated from the cell resulting in different orientations.

for example, that K^+ channels are 1000 times more selective to K^+ than to Na^+ . According to their selectivity, ion channels are classified as K^+ , Na^+ , Ca^{2+} , Cl^- , and H^+ channels.

The current flow through a channel is determined by the open-channel amplitude and by the relative time the channel stays open. As illustrated in the characteristic example in Figure 3, all channels fluctuate in a stochastic manner between an open and a closed state. In the simplest case, the mean dwell time of the open and the closed states are single exponentials so that the probability of a channel to be open (P_o) is given by

Figure 3 Example of single-channel fluctuations of K^+ channel. Opening of the channel pore allows a current flux of constant amplitude. The length which a channel spends in the open or closed state is variable. In the simplest case, the channel fluctuates in a stochastic manner with k_1 and k_{-1} between open and closed states.

$$P_o = \tau_o / (\tau_o + \tau_c) \quad [1]$$

where τ_c and τ_o are the time constants for the closed and open times respectively.

While this simple kinetic model is suitable for the description of most channels, a detailed analysis of many ion channels has shown much more complex kinetic models. The analysis of the single-channel open and closed dwell times thus has led to models which include many more closed and open states organized in serial and/or parallel arrangement.

One of the important features of ion channels is that they are regulated. This guarantees that their activity is well integrated into the general physiological functions of a cell. In order to increase or decrease the current flux, channels increase or decrease their open probability, respectively. An increase in open probability can be achieved via a prolongation of the mean open dwell times or by a shortening of the mean closed dwell times or by both.

Several factors have been found to regulate ion channels in the physiological context. These include physical factors such as membrane voltage and mechanical stress. In addition, a large number of chemical modifications acting from either side of the membrane are known. Figure 4 illustrates as an example the regulation of channel activity performed by pH on one side of the membrane. The data show that lowering of the pH results in a prolongation of the closed times, while the open times are not affected. As a result, the activity of the channels drops in a pH-dependent manner. This is mostly due to a titratable amino acid in the channel protein. As in the case of modulation by pH, most channel proteins harbor specific binding sites for their modulators.

Several different channels have been found to be regulated by chemical modification. The more general factors known to regulate channel activity in the plasma membrane of cells from the cytoplasmic side are, for example, phosphorylation/dephosphorylation, Ca^{2+} , pH, and cyclic nucleotides.

So far, the function of ion channels only at the single-protein level have been seen. From this information, one can easily extrapolate to the behavior of the ensemble of many channels of the same type in the membrane. From the aforementioned channel function, it can be deduced that the time-averaged current (I) through a channel is given by the product of the single-channel current (i) and the open probability (P_o):

$$I = i P_o \quad [2]$$

In this sense, the statistically weighted open-channel current is a perfect representation for the ensemble of the same kind of channels in a membrane. This only needs to be multiplied by the real number of channels in the membrane (N) to obtain the entire behavior of all channels in the membrane:

Figure 4 Effect of different pH on single K^+ channel gating. Activity of the same channel measured with a different pH on the cytoplasmic side of the membrane patch. Note that acidification increases the duration of the closed state.

$$I = i^+ P_o^* N \quad [3]$$

From an experimental point of view, it is sometimes more convenient to measure and analyze directly the ensemble currents in a membrane without any attention to the single channels. This can be achieved as illustrated in Figure 5. In this patch clamp configuration, referred to as “whole cell” configuration, the sum of currents through the ensemble of ion channels in the membrane is recorded. But in essence, the data between the statistical analysis of a single channel and the recording of ensemble currents are interchangeable.

Structure and Function of Transport Proteins

The first information on how membrane transport devices work came from physiological flux measurements. Physiologists traditionally divided transport mechanisms into two classes, carriers and pores. Carriers were responsible for transport which at high substrate concentration reached saturation, while pores were identified as mediating membrane transport which did not show any saturation kinetics. A carrier was essentially viewed as a molecule diffusing back and forth across the membrane while carrying small molecules or ions bound to specific sites, whereas a pore was a narrow, water-filled tunnel, permeable to few ions and molecules small enough to fit through the hole.

The numerous membrane proteins which have been purified, and the related genes which have been cloned, show that the carrier proteins are too large to diffuse or spin around at the predicted rate. The new view of carrier transport is that the protein is fixed in the membrane while exposing the transport-binding sites alternatively at the two sides of the membrane by small motions. Although the first crystal structure of a carrier appeared in the year 2000, nevertheless the specific mechanisms by which several carrier devices (transporters and pumps) work still await to be proved combining different experimental approaches, such as electrophysiology, molecular biology, and crystallography.

The view of pores as water-filled tunnels has been firmly established for a class of proteins which is now known as ion channels. The early identification of these pores as proteins that span the membrane and the subsequent identification of the genes that codify for them have focused the work of electrophysiologists, biophysicists, and molecular biologists since the 1980s on ion channel structure–function relationships, creating a solid background of knowledge on how these channel proteins operate. The understanding of the structure and function of ion channels culminated in the landmark determination of the crystal structure of a K^+

Figure 5 Relationship between single-channel activity and ensemble membrane current. Single-channel fluctuations (d) from a cell-attached recording (c, see Figure 2). The three simulated channel fluctuations are responses to a depolarizing voltage step (from (-)V to (+)V). The ensemble current (b) is obtained by averaging 30 sweeps as in (d). The same ensemble current (as in (b)) would be measured in the recording configuration illustrated in (a). Here the membrane underneath the patch pipette is ruptured to give a low resistance access to the cell interior.

channel, the bacterial channel KcsA, by Roderick MacKinnon. For his work on structure determination of several bacterial K⁺ channels, MacKinnon received the Nobel Prize for chemistry in the year 2003.

The atomic structures of K⁺ channels have especially improved the understanding of two main properties of ion channels: selectivity and gating.

Selectivity

A potassium channel can conduct K⁺ ions one thousand times better than Na⁺ ion. It is assumed that, in order to allow the protein channel to discriminate one ion from the other, the ions have to pass the cell dehydrated. In this situation, the atomic ray of Na⁺ is smaller than that of K⁺ (0.95 Å and 1.3 Å, respectively) implying that the Na⁺ ions are not excluded on the basis of their dimension and that the selection process probably involves some kind of interaction with specific binding sites in the protein. The second striking characteristic of K⁺ channels is that they pass K⁺ ions at high speed, 10 e6, close to the diffusion limit. How can a protein interact with an ion and nevertheless allow its passage at the speed of ion diffusing in water? The atomic structure achieved for the bacterial potassium channel KcsA provides a deep understanding of K⁺ selectivity and the ion conduction process.

Figure 6 reports the structure of the KcsA channel. The K⁺ channel pore is formed by four identical subunits surrounding a central ion conduction pathway (two of the four subunits are shown in Figure 6a). Each subunit contains two transmembrane α -helices, termed inner (nearest the ion pathway) and outer helices, and a tilted shorter pore helix (in red) pointing toward the ion pathway and keeping in place the selectivity filter (in gold). The selectivity filter discriminates between potassium and other ions. It is the narrowest part of the ion permeation pathway, and is located in the extracellular third of the ion pathway. Inside the selectivity filter, the K⁺ ion encounters four binding sites, which are created by evenly spaced layers of carbonyl oxygen atoms and a single layer of threonine hydroxyl oxygen atoms. At these sites a K⁺ ion binds in a dehydrated state, surrounded by eight oxygen atoms from the protein, four "above" and four "below" each ion (Figure 6b). The arrangement of protein oxygen atoms in each binding site is very similar to the arrangement of water molecules around hydrated K⁺ ion observed in the central cavity (Figure 6b). Potassium ions therefore diffuse from water into the selectivity filter where the energetic cost of dehydration is compensated. Sodium ions, on the other hand, do not enter the selectivity filter because the dehydrated Na⁺ ions have a radius of 0.9 Å, and their coordination is precluded in this rigid structure. The precise ion coordination required for selectivity does not prevent their rapid diffusion through the pore. This is due to the fact that the selectivity filter contains more than one ion and the repulsion between closely spaced ions helps to overcome the affinity that each ion has for its binding site.

Gating

While the pore of a channel is designed to achieve minimal energy barriers to ensure a fast flow rate, other parts of the channel are responsible in determining whether the channels are open or closed, and they do so by propagating conformational changes to the ion-permeating pathway inside the pore. Potassium channels differ in relation to the various ways in which they are gated, that is, the way they change from a nonconductive to a conductive state. Some K⁺ channels are ligand-gated, which means that the pore opening is energetically coupled to the binding of an ion, a small organic molecule, or even a small protein. Other K⁺ channels are voltage-gated, and the pore opening is energetically coupled to the movement of a charged voltage sensor within the membrane electric field. Diversity in gating is achieved by diverse structural domains attached in a modular fashion to the conserved pore domain. Binding of ligands as well as displacement of the voltage sensor by voltage changes must result in a global conformational change of the channel protein which is eventually transduced to the pore unit, causing the pore to open (and close). The recent

Figure 6 Ion conduction through a potassium channel pore, as deduced from the crystal structure of the bacterial channel KcsA. (a) Two of the four subunits from the pore of KcsA are shown, with the extra cellular side on top. Each subunit is formed by an outer helix that contacts the lipid membrane, an inner helix that faces the permeation pathway, a pore helix (red), and a selectivity filter (yellow). Blue mesh shows electron density for K⁺ ions (green) and water molecules (red) along the pore. (b) Enlargement of the selectivity filter showing four dehydrated K⁺ ions inside the filter and one hydrated K⁺ ion outside (bottom). crystallization of several K^+ channels (both in the open and closed conformation) has explained the conformational changes which underlie the pore opening in K^+ channels.

The pores of KcsA, crystallized in the closed configuration, and MthK, crystallized in the open configuration, are compared in Figure 7. The prominent difference between these two structures is the position of their inner helices. In KcsA they form a bundle at the cytoplasmic side of the pore that prevents free ion flow, while in MthK the inner helices are bent at a hinge point, allowing free ion flow between the cytoplasm and the selectivity filter. These structures are probably representative of the closed- and open-pore configurations of many different K^+ channels, as suggested by the amino acid conservation in the inner helices sequences of all K^+ channels (in particular of a glycine at the hinge point) (Figure 7).

The Cell Membrane as an Equivalent Circuitry of Parallel Ion Channels with Variable Conductance: An Explanation for Complex Changes of Membrane Voltage

In this section, the functional roles of ion channel proteins are discussed with the aim of integrating their individual properties. This aims to explain their concerted contribution to the overall cell activity.

The concerted activity of ion channels may here be described for electrically excitable cells such as neurons and muscle cells. In general these cells can be found in two different conditions, namely at rest or excited. In the resting condition, the cell membrane voltage is stable over long periods of time; during electrical excitation, the cell undergoes a transient depolarization, a phenomenon called action potential (AP).

Both situations can be explained by a dynamic interplay of different ion channels in the plasma membrane. A physical model of the main elements in the plasma membrane of such a cell is presented in Figure 8 where an equivalent circuit of a cell membrane built on capacitance, variable resistors, and batteries is presented. In this simple circuit, each resistor represents a specific type of ion channel, that is for K^+ or Na^+ , with a variable internal resistance. The branch with the conductance g_L represents the ensemble of other conductances such as channels for Cl^- and Ca^{2+} . The variability of the resistor reflects the ability of the ion channels to undergo changes in activity. An important detail of this model is that the activity of the channels is sensitive, in a distinct way, to

Figure 8 Electrical circuit representing the cell membrane. The lipid bilayer is modeled by a capacitance (C_M), while the different families of ionic channels are represented by conductances (g_x). The electromotive forces (E_x) generated by asymmetric ionic concentrations are included in the battery elements. Note that g_{Na} and g_K are variable conductances due to their time and voltage dependence.

voltage. Hence through the voltage coupling of the channels via the membrane, the activity of each channel has an effect on the activity of the others. Due to their different distribution across cell membranes, the main ionic species involved in electrical activity (i.e., Na^+ , K^+ , Ca^{2+}) have different thermodynamic equilibrium (see Figure 1). These electrochemical gradients are a source of potential energy. In the model they are represented by specific battery voltages, which are determined by the Nernst potential (E_x) of the respective ion. Cells consume this energy difference when ionic channels open and ions can freely diffuse. Due to its dielectric properties, the lipid component of the cell membrane is represented by a capacitor (C_M). Large and fast changes in the membrane voltage will hence cause currents to charge this capacitor.

At rest, cells have an internal potential of $-60/-80$ mV with respect to the extracellular environment. The precise value of the resting potentials is determined mainly by two factors: a relatively high K^+ (g_{K^+}) and Cl^- (included in g_{L}) permeability of the cell membrane due to active K^+ and Cl^- channels and the respective battery voltages of E_{Cl} and E_{K^+} . E_{Na^+} does not contribute to the resting voltage since Na^+ channels are generally closed at rest ($g_{\text{Na}^+}=0$). Hence, the membrane current (I) at rest can be described according to the Ohms law by

$$I = g_{\text{K}^+} (V - E_{\text{K}^+}) + g_{\text{Cl}^-} (V - E_{\text{Cl}}) \quad [4]$$

This resting state is drastically modified when cells become electrically active, that is, when they fire an AP. A simple physical description of an AP would be a wave of potential that travels at a rate of $1-100 \text{ m s}^{-1}$ along excitable membranes, and conveys information from one point to another. The peak of the moving wave corresponds to a physical location where the membrane polarity is inverted (the intracellular part is positive up to $+40/+60$ mV with respect to the external), while the adjacent regions are still (region ahead) or have already returned (region before) to the resting hyperpolarized value.

The Hodgkin and Huxley (HH) model presented the first mechanistic explanation of the AP. This original model has now undergone major revision; however, the basic ideas can still be used to unravel how the concerted work of different ionic channels can bring about the AP. HH's interpretation of the molecular mechanisms underlying the complex event of an AP consists of a voltage-coupled interplay of two conductances: the Na^+ and K^+ channels. The elements that confer the circuit its active properties (i.e., the capacity of generating an AP) are the variable conductances (g_x) which are disposed in parallel (Figure 8). In the original HH model, the number of conductances is limited to three: g_{Na} and g_{K} that are the true, time- and voltage-dependent components, and a fixed g_{L} that represents a pathway for leakage currents. The last elements to consider are the source of electromotive forces E_x which complete each conductance branch with the electrochemical energy associated with the specific ionic flow and determined by the Nernst equation. The two dominant elements, the Na^+ and K^+ channels, have very distinct voltage- and time-dependent properties which can be summarized as follows: the Na^+ channels open transiently very fast upon a depolarization of the membrane. The K^+ channels in contrast open slowly upon depolarization. Because of their electrocoupling, the activity of one reflects back on the other and vice versa. Once the appropriate set of time- and voltage-dependent variables for each channel is defined, the mathematical solution of the circuit will appropriately simulate the electrical activity of the cell.

A more intuitive description of an AP can be attempted by describing the events that take place in a membrane region that is invested by an AP wave. If one could take a look at the intracellular side of the membrane, a situation would be observed where an already depolarized, positively charged region, is followed by a region in an electrically resting state of about $-70/-80$ mV. This situation would generate a depolarizing flow of positive charges toward the negative region; this event is the key element in the generation of APs. If the depolarization is not strong enough, then the resting K^+ conductance will soon buffer this perturbation and reestablish the correct resting potential, but if the depolarization reaches a threshold it will trigger a cascade of events that generates an AP. This is the reason why biophysicists describe the AP as an all-or-nothing event. It has already been seen that a great number of ion channels are gated by voltage, and this concept is crucial to the understanding of the AP mechanism. The threshold corresponds to a critical value of potential at which Na channels start opening, and thus generate an inward-going current that further depolarizes the membrane by a positive feedback mechanism that drives the membrane potential toward the equilibrium of Na^+ ions (E_{Na}). This depolarization activates two additional events: the inactivation of Na^+ channels and the activation of K^+ channels. Na^+ channels are dually gated by voltage: the positive electric field acting on these transmembrane proteins initially induces a conformational change that forces the channels to an open, conductive state, but soon after the channels relax to a nonconductive state. The voltage-gated K^+ channels involved in the AP differ from the resting ones in that the former are normally closed at resting, but open upon depolarization. K^+ channels activate with a slower kinetics compared to that of Na^+ channels, and, according to the acting electrochemical gradient, they generate an outward-going K^+ ions efflux, that repolarizes the cell to the resting state, and thus terminate the AP signaling. The electrical activity of a cell can now be summarized in three general components: first, a trigger phase that moves the potential to the threshold; second, the activation of an inward-going current that rapidly depolarizes the cell, and finally the third part driven by a potassium outflow that terminates the electrical event. The above events are an over-simplification of a reality that is often more complex and thus adaptable; nature has evolved molecules with slightly different properties so that an array of elements is available to better accomplish the different functional requirements of excitable cells. Indeed APs can simply represent a piece of information that needs to be transferred from one point to another with high fidelity, but in many cases they must locally trigger crucial events such as a neurotransmitter release or a muscle contraction. Often, when spatial transferring of information is required, a simple system, based on limited population of channels (HH model), is perfectly fit for the function. Neuronal exocytosis and muscle contraction require the contribution of at least one more class of channels: the Ca^{2+} channel family. Ca^{2+} ions are key elements in inducing both the synaptic release machinery, and in allowing the physical interaction between the sliding filaments of muscle fibers.

Ion channels can be largely modulated by several effectors, for example calcium, second messengers such as cyclic nucleotides, phosphorylation, interaction with other proteins, and more (see above). As an example of the functional importance of these modulations, the activity of cardiac pacemaker cells are described here (Figure 9). These cells exhibit spontaneous voltage oscillations (Figure 9a) that determine the cardiac rate.

The most striking property of these cells is the slowly depolarizing or pacemaker phase (between arrows in Figure 9a) that, while moving the cell membrane toward the threshold (dotted line), allows for cardiac chamber refilling. This phase is generated by the intervention of several ionic channels and transporters, with the most important one being a specific current named I_f or pacemaker current. The I_f is modulated by the neural autonomic system that can increase (sympathetic branch) or decrease (parasympathetic branch) the current availability at any given potential (Figure 9b). The functional effect of this modulation is the modification of the slope of the diastolic depolarization that becomes steeper or shallower thus determining the autonomic-induced modulation of the heart rate (Figure 9a).

So far, the role of ion channels in underlying important physiological functions have been described; one can now appreciate why ion channels are important targets for drug-based therapy. Indeed in the year 2003, 15% of the top 100 best-selling drugs on the market were designed to specifically interfere with ion-channel proteins. Several diseases such as epilepsy, long QT syndrome, cystic fibrosis, myopathies (but the list is in constant expansion) have been found to depend on abnormalities of genes coding for these proteins. For this reason, a new group of diseases has now been named after their molecular origin channelopathies. A still far

Figure 9 Heart rate modulation by autonomic system. (a) Spontaneous APs of pacemaker cells in control and during autonomic-induced modulation. (b) Fractional availability (y -axes) of the pacemaker current as a function of the applied voltage. The amount of available current modifies the slope of the pacemaker depolarization and thus the heart rate. (Modified with permission from Accili EA, Robinson RB, and Di Francesco D (1997) Properties and modulation of I_f in newborn versus adult cardiac SA node. *American Journal of Physiology, Heart and Circulatory Physiology* 272: H1549–H1552; and from Accili EA, Proenza C, Baruscotti M and Di Francesco D (2002) From funny current to HCN channels: 20 years of excitement. *News in Physiological Sciences* 17: 32–37; The American Physiological Society.)

to come, yet enticing possibility, is a strategy devised by ion-channel biologists which is based on the “use” of ion-channel proteins as molecular tools for therapy of cardiac rhythm alteration. To date, cardiac electronic pacemakers have been widely used in the treatment of rhythm disorders. However, recent research suggests the possibility of developing therapeutic approaches based on “biological pacemakers” in which the ability of generating spontaneous cardiac electric activity could be restored by manipulating the level of ion channels expressed in a specific desired region of the heart.

Introduction

Electromagnetic phenomena play an important role at all hierarchical and structural levels of biological organisms and even in interactions among organisms and their orientation within the biosphere. Electromagnetic fields in cells and tissues may be inherent to the biological system or the result of natural or man-made exposure to such fields. Fields may interact with electrically passive or active biological structures. In both cases, the response by specific mechanisms will depend on field frequency and intensity. Whereas external fields may range from electrostatic fields up to Gamma-irradiation, the generation of fields in cells is limited in frequency range and intensity. The frequencies of physiologically generated electromagnetic fields range from 0 Hz for static (DC-) fields up to light frequencies for fluorescence effects driven by captured photons or ATP, as is the case with lightning bugs.

In this article, the electric and magnetic properties of biological matter will be considered for frequencies ranging from DC up to GHz. The focus will be electric phenomena, since the interaction with magnetic fields is usually weak for the generally low magnetic susceptibility of biological matter. Also impedance and AC electrokinetic techniques will be considered as methods that apply fields for exploring the passive properties of tissues and suspended cells. To focus on tissues and cells specific mechanisms discussed in relation to speculations of possible harmful effects of electromagnetic fields will not be considered. Neither will fields be considered beyond GHz in the far infrared or visible light ranges.

Mechanisms and Frequencies of Field Generation and Interaction

At the atomic and molecular levels, static electric fields associated to ions and dipole molecules are important for intermolecular forces. At the next higher structural level, static fields are found in electric double layers such as at the interfaces of membranes with aqueous electrolytes. Whereas these fields are part of the thermodynamic (electrochemical) equilibrium at the interface, the (nonequilibrium) physiological transmembrane potential of living cells is built up by ATP-driven ion pump proteins. Other nonequilibrium processes are found in electro-rheological effects as motion of fluids in or around cells and tissues, and in the deformation of tissue leading to a piezo-like effect, as in bones, for instance. Even though the transmembrane potential cannot usually be measured in the external medium, in some cases static fields can be detected around single cells or even organisms, for example, the DC potentials between various parts of an animal body or of plants. In lesions, wound potentials are found.

Cell excitation, as in nerve and muscle cells, is based on active electric cell properties. Voltage gated ion channel proteins play the key in the generation of membrane potential spikes. Spike frequencies reach the kHz range. In excitable tissues, such as the brain, so called "field potentials," superimposed potentials generated by a great number of cells, are found. Such potentials are detected in medical diagnostics in electromyograms, electrocardiograms, or electroencephalograms (EMG, ECG, or EEG), for example. Between limbs, ECG potentials of several mV are detected.

Even though mechanical oscillations in the lower radio frequency range are common for ultrasound orientation of animals, the emission of electromagnetic fields by biological systems in the radio frequency range is unknown. Nevertheless, the hair cells of the inner ears of these animals or the sound detecting cells in insects must of course be capable of electrically processing these frequencies.

Beyond the radio frequency range, spectroscopic methods detect molecular properties. In the microwave and far infrared regions energy transitions (the absorption and emission of energy quanta) are particularly related to the rotation of molecules. Oscillations inherent to the molecules possess higher energies and are subsequently detected in the near infrared range. The highest energies are associated with the electrons of the molecules. The corresponding energy transitions are mediated by quanta of the visible and ultra-violet optical ranges.

It is generally believed that vibrations of molecules and the related oscillations of their electronic clouds are not synchronous and generate localized fields of low strength. Nevertheless, these fields mediate inter- and intramolecular interaction forces (van der Waals forces). Since physiological energy is steadily degraded by chemical reactions, which leads to a warming, living organisms radiate electromagnetic energy of the infrared frequency range into the environment.

The exploration of the properties of biological matter has always been connected to medical and biotech application of electromagnetic fields. For the response of cells to electric fields, both the passive properties of the different media as well as the active properties of various membrane proteins, such as ion pumps and exchangers, are of importance. The patch clamp technique

has revolutionized the exploration of protein channels, another class membrane proteins. Muscle and nerve stimulations as well as hyperthermia are well established in medical therapy. Electric cell transfection by foreign DNA and the production of hybridoma cells by fusion are based on membrane poration by large induced transmembrane potentials. New biotech applications such as the development of a lab-on-chip technology are based on a combination of single cell techniques and AC-electrokinetics.

Passive Electric Properties of Biological Matter

An electric field E passing through a medium is weakened by a factor that is given by the absolute value of its relative complex permittivity $|\epsilon^*|$. The electric displacement D^* is constant:

$$D^* = \epsilon^* \epsilon_0 E \quad (1)$$

For such parameters, a phase shift may appear in between the exciting field or voltage and the resulting displacement or current. ϵ_0 stands for the permittivity of vacuum. The asterisk denotes complex parameters. As a result the material parameters, for example, ϵ^* , consist of a real (ϵ' -in-phase) and an imaginary (ϵ'' -out-of-phase) part. The capacitance of a medium with a relative permittivity ϵ^* that is located in between two parallel electrodes of distance d and area A is

$$C^* = \frac{1}{\epsilon^* \epsilon_0} \frac{A}{d} \quad (2)$$

For thin films like membranes a sectoral capacitance $C_m = C/A$ can be defined. When C_m values are given in the literature in most cases a possible frequency dependence is neglected. Often the passive electric properties of biological matter are described by its impedance Z^* , that is the generalized, frequency dependent resistance:

$$Z^* = \frac{1}{\sigma^*} \frac{d}{A} \quad (3)$$

This describes the impedance of a medium with a specific conductivity σ^* that is located in between two parallel electrodes of distance d and area A . In the simplest case, the medium is homogeneous and isotropic like aqueous electrolytes. In contrast, biological tissue is structured, for example, by cell membranes. This compartmentalization is the reason for structural dispersions.

Dispersions

The impedance of biological material is characterized by a variety of characteristic frequency dependent changes. These changes base on the fact that permittivity contributions of certain relaxation processes, which follow the external field at lower frequencies, disperse at higher ones. Consequently, the permittivity of biological material drops by several orders of magnitude over some frequency decades. A permittivity drop at a given frequency corresponds to a certain conductivity increase since the field-induced movement of bound charges can no longer be distinguished from the movement of charges, such as ions, that are already free to move at DC.

Researchers tried assigning the measured dispersions to certain biological structures on the different hierarchical levels and to classify the contributing processes. For classification, two different approaches were chosen – the dispersions were either sorted according to their physical nature, for example, as Maxwell–Wagner and Debye dispersions, or according to the frequency range wherein they occur. While Maxwell–Wagner dispersions base on the structuration of the material, Debye dispersions are related to the orientation of molecular dipoles. A classification according to frequencies yielded a scaling where the dispersions with increasing frequencies were assigned to the α -, β -, and γ -range (Fig. 1). It was assumed that well-defined processes are responsible in a certain dispersion range.

Despite their low frequencies, analysis of the α -dispersions in the sub-1 kHz frequency range is especially difficult. Many different processes may overlap, including such processes as electrode processes, hydrodynamic relaxation of electroosmotically induced convections within the measuring chamber and around the cells, membrane channels, cell orientation and deformation, as well as cell electrophoresis. The difficulty is that these phenomena are hard to separate, and concurrently influence suspension medium and cells (Fig. 2).

In tissues and cell suspensions the major contributions of the β -dispersion stem from structural polarizations as those of the cytoplasmic membrane or of internal membrane systems, as well as the polarization of the cytoplasm. It is to be noted that membrane and cytoplasmic dispersions are of different qualities. Whereas membrane dispersions are based on the capacitive bridging of the thin membrane film, the cytoplasmic dispersions are mediating the switching from a field distribution, according to the conductivities, to a distribution according to the permittivities of the bulk media. The structural dispersions may be influenced by the dispersion of other processes, such as the surface conductance or dipole relaxation of large molecules. In cellular systems, Debye dispersions of proteins usually occurring around 1 MHz are masked by the structural membrane dispersions.

Fig. 1 Schematic frequency dependence of the relative permittivity of tissue or cell suspensions according to H.P. Schwan *et al.*

In the γ -range above 100 MHz, quick dissociation-association relaxation or Debye dispersions of small molecules or charged groups must be expected. The dielectric properties of proteins are believed to be important for their physiological function such as protein-protein association or the interaction with charged ligands. Dispersions between 200 MHz and 10 GHz were assigned to bound water and small molecules (δ -dispersion). Dispersion over 10 GHz can mainly be assigned to free water.

Properties of Aqueous Media

Aqueous Electrolytes

The intracellular space and the cytoplasm can be considered aqueous solutions of ions and organic molecules. Up to GHz frequencies, their properties are often simplified to those of aqueous electrolytes that can be described by frequency independent specific conductivities and permittivities. For electrolytes, the conductivity σ and relative permittivity ε are based on ionic conduction and the permittivity of water, respectively. Whereas the permittivity of water of 80 at 18° C shows a slight decrease with temperature and ion concentration, the conductivity may vary by orders of magnitude. For solutions of one salt, it can be calculated from salt concentration and equivalent conductivity. These relations are more complex for mixed solutions. Accordingly, the complex specific conductivity σ^* consists of the frequency-independent contribution of ion conduction and frequency-dependent displacement currents based on the water permittivity

$$\sigma^* = \sigma + j\omega\varepsilon\varepsilon_0 \quad (4)$$

where ω and j stand for the circular frequency of the field and $\sqrt{-1}$, respectively. After introduction of Eq. (4), Eq. (3) describes a system that consists of a resistor (for the ion current) in parallel to a capacitor (for the displacement current). Accordingly, the impedance of the medium steadily decreases with frequency.

Cytosolic Proteins

The cytoplasm of most cells is extremely rich in proteins influencing the electric properties. Proteins reduce the water concentration resulting in a reduced ion mobility and conductivity. The reduction factor may be higher than 2 in red cells. A second contribution comes from the proteins themselves. Because of their high dipole moments, they are the cause for extraordinary high permittivities at low frequencies. Nevertheless, their bulky structure is incapable of following the orientation force of an external field beyond a certain frequency. This is the reason for dielectric dispersions, that is, the decrease of ε , by the dielectric decrement, and a corresponding increase in σ , which are typically in the frequency range around 1 MHz. The dispersion in pure protein suspensions can be considered to be Debye dispersions, which were extensively investigated. In tissues and cell suspensions, protein dispersions are masked by the structural dispersions. Therefore, dispersions of cytoplasmic proteins were predominantly investigated after cell lysis or in cell free suspensions.

Fig. 2 Polarization processes based on various biological structures. The size of the polarized structures and the physical nature of the dispersion processes determine their characteristic times and frequency dependencies. The first column summarizes the structural levels and theoretical approaches for describing dispersion processes. The sketches in the second column present examples for processes that are designated in the third column.

Passive Membrane Properties

Sectoral Capacitance

Membranes are known to be inhomogeneous and anisotropic. For a membrane, solely composed of a lipid double layer, a specific capacitance of $\sim 0.75 \times 10^{-3} \text{ F/m}^2$ can be estimated. Nevertheless, biological membranes are rich in membrane spanning proteins. Thus, protein and lipid areas form a parallel circuit of two capacitors, resulting in a specific capacitance of about 10^{-2} F/m^2 at frequencies below 1 MHz. Accordingly, protein regions present areas of higher specific capacitance. The various regions of the membrane, that is, bound water layers, lipid headgroup regions, the hydrophobic lipid chain regions as well as the orthogonal segments formed by transmembrane proteins, will exhibit a different frequency-dependent dielectric behavior. The glycocalix surface layer made up by charge-carrying polysaccharides that are bound to membrane lipids and proteins is of special importance for the α -dispersion.

Lipid Region

The lipid regions of membranes have an overall thickness of 4–5 nm with roughly 0.8 nm at each side being occupied by the headgroups. The hydrophilic headgroup regions contain the strong P–N dipoles, the ester bonds of the fatty acids and the glycerol backbones. Together with the associated water molecules, dipole potentials as high as 240 mV (positive at the membrane surface) are generated. In normal direction, the relative permittivity drops from ~ 78 in the bulk water to ~ 2 in the fatty acid chain region. The permittivity of ~ 30 in the headgroup region disperses with a decrement of ~ 28 . In tangential direction, experimental and theoretical results hint on relative permittivities as high as 300 to 400 with a dispersion that is related to the in-plane orientation of the headgroups. For both orientations, dispersion occurs around 50 MHz resulting in a high frequency permittivity of ~ 2 . Due to its low permittivity already at low frequencies, the fatty acid chain region is highly hydrophobic, forming the major energetic barrier for the permeation of ions and small polar molecules. For a spherical ion, this barrier arises from the difference of its electric surface potentials inside the lipid and aqueous phases, which differ by the quotient of the ϵ -values of the two phases.

Membrane Proteins

Intercalation of proteins in the membrane relies on a microenvironment of specific dielectric properties. Nonpolar amino acids form the protein surface where it is exposed to the lipid chain region. Highly polar protein groups as loops and tails of the polypeptide chains are exposed to aqueous surfaces. They possess a higher degree of molecular freedom suggesting higher permittivities. The peptide bonds of the membrane part of most proteins are very rigid. Their highly restricted mobility results in a low permittivity. Up to low kHz frequencies, the protein mediated ion transport is also of importance for electric protein properties.

Bound Water

The thickness of the bound water layers is ~ 0.5 nm, with 11–16 water molecules per lipid. About four water molecules per lipid are tightly bound and strongly oriented. More distant water molecules show a smoothly decreasing orientation profile. The average permittivity of the bound water layer is ~ 60 . The dispersion frequency will depend on binding strength with higher frequencies for lower binding strengths.

Impedance and AC-Electrokinetic Phenomena

Impedance experiments provided the first proof for the existence of biological membranes. Impedance experiments analyze the frequency dependent electric response to an applied field to explore dielectric properties of tissues and cells. The electric response is based on the polarization of the sample structures, like suspended cells. Single cell polarization may lead to orienting, deforming, moving or rotating in AC-electrokinetics. The different motions depend on the different spatial properties of the field determining its interaction with the polarized cell. The frequency dependence of each effect is related to the frequency dependence of the polarizability of the various constituents of the cell. All effects are exploited in cell characterization methods: electroorientation, electrodeformation, dielectrophoresis, and electrorotation. For modeling the effects, the induced cell dipole moment is obtained by integrating over the local fields of all subcellular structures in the cell volume. As in the case of impedance, models for multishell spherical, cylindrical and ellipsoidal geometries are readily available.

Generally, the force experienced by the cell is related to the induced dipole moment m^* , which is the volume integral of the cell's polarization.

$$m^* = (m_a \ m_b \ m_c) = \epsilon_e \epsilon_0 V (f_{CM}^{*a} f_{CM}^{*b} f_{CM}^{*c}) E \quad (5)$$

Along the semiaxes, its frequency-dependent part is given by the components of the Clausius–Mossotti factor f_{CM}^* . Its a-component is given by

$$f_{CM}^{*a} = \frac{\epsilon_i^* - \epsilon_e^*}{\epsilon_e^* + (\epsilon_i^* - \epsilon_e^*) n_a} \quad (6)$$

The permittivities of the external and internal media are marked by indices e and i , respectively. n_a is the depolarizing factor along semi-axis a . Depending on the ellipsoidal shape, n_a can vary from 0 to 1. Please note that Eq. (6) simplifies in structure to the left side of Eq. (7) for spherical objects with $n_a = 1/3$.

For an ellipsoidal cell with confocal layers, for each field frequency, a Maxwellian equivalent body can be found that exhibits the same complex dipole moment m^* . The equivalent body has homogeneous medium properties and a constant local field.

The impedance of suspensions of randomly orientated three-axial single-shell cells is described by the Maxwell–Wagner mixing equation, which can be written in the form

$$\frac{3(\sigma_s^* - \sigma_e^*)}{\sigma_s^* + 2\sigma_e^*} = \frac{p}{3} (f_{CM}^{*a} + f_{CM}^{*b} + f_{CM}^{*c}) \quad (7)$$

where p is the volume portion of the suspended cells. σ_s^* is the complex specific conductivity of the cell suspension, ie, the inverse of its specific impedance in Ωm . For objects oriented with semiaxis a in the external-field direction we obtain:

$$\frac{3(\sigma_s^* - \sigma_e^*)}{\sigma_s^* + 2\sigma_e^*} = pf_{CM}^{*a} \quad (8)$$

The impedance of oriented single cells can be detected in microfluidic devices. For a population of suspended cells, synchronous reorientations will be detectable as impedance transitions. Such reorientation can be induced, for example, by electro-orientation in DC or AC fields, as well as in optical, acoustic or hydrodynamic fields. For the specific conductivity of a suspension of spherical cells ($a=r$), the analytical expression

$$\sigma_s^* = \sigma_e \frac{2\sigma_e + \sigma_i + 2p(\sigma_i - \sigma_e)\omega r C_m^{spec} - 2j\sigma_e\sigma_i(1-p)}{2\sigma_e + \sigma_i - p(\sigma_i - \sigma_e)\omega r C_m^{spec} - j\sigma_e\sigma_i(p+2)} \quad (9)$$

can be obtained. Neglecting the membrane conductance, it allows for deriving the characteristic circular frequency of the suspensions ω_c^{IMP} in the membrane dispersion frequency range

$$\omega_c^{IMP} = \frac{1}{rC_m} \frac{2\sigma_e\sigma_i}{2\sigma_e + \sigma_i} \left(\frac{2\sigma_e + (1 - \frac{3}{4}p)\sigma_i}{2\sigma_e + \sigma_i} \right) \quad (10)$$

For infinite dilutions ($p=0$), the equation corresponds to Eq. (14) for spherical cells.

AC-electrokinetic methods yield similar information, as does impedance, though with a lower resolution with the latter. A rotating field induces a dipole moment, which rotates at the angular frequency of the external field. A spatial phase shift of the external field vector and the induced dipole moment, caused by any dispersion process, gives rise to a torque generating individual cell rotation. For example, the membrane dispersion generates a cell-typical electrorotation peak. Interestingly, the torque and therefore cell rotation is at maximum if relaxation time of the dispersion process and external field frequency match ($\omega = \omega_c$, see below). For their high resolution, dielectric single cell methods are of special value for cell characterization and the determination of the field distribution at the subcellular level. All AC-electrokinetic phenomena can also be used for cell or molecule manipulation. They form the basis for the lab on chip technology.

The Induced Transmembrane Potential ($\Delta\Phi$)

Electric cell transfection and cell fusion are routine biotech applications basing on membrane poration by high induced $\Delta\Phi$. For poration DC or AC fields have to be applied for a sufficiently long time or at a sufficiently low frequency, respectively. Pore induction is a strongly nonlinear process mimicking a "critical" membrane voltage of ~ 1 V corresponding to ~ 200 MV/m in the lipid phase. $\Delta\Phi$ is proportional to the external field strength and depends on cell size, shape, orientation and electric cell properties.

Since the 1920s of the last century, physicists and chemists have been dealing with the potential induced on the surface of cavities or bodies, to describe the dependence of the local field deviation on the shape of the bodies or cavities. H. Fricke was the first to apply the physical knowledge on the depolarizing factors of ellipsoidal bodies or cavities to express the induced transmembrane potential $\Delta\Phi$. For a cell of the general ellipsoidal shape with semiaxes a , b , and c , at the pole of semiaxis a , a $\Delta\Phi$ of

$$\Delta\Phi = \frac{1}{1-n_a} aE = a_{infl}E \quad (11)$$

is induced. a , n_a , and a_{infl} stand for the length of the semiaxis oriented in field direction, the depolarizing factor along semiaxis a , and the influential radius, respectively. Please note that only the field component, which is oriented along semi-axis a contributes to $\Delta\Phi$ at pole a . The equation applies for the DC steady state and a cell with zero membrane conductance. Along each semi-axis, the parameter "influential radius" depends solely on the shape of the ellipsoidal body. For a vacuum body, it describes the distance between its center and that undisturbed equipotential plane, which touches the pole in the presence of the body.

For a sphere, $a=b=c=r$, and $n_a=n_b=n_c=1/3$ since the sum of the three factors along the three principal axes is always unity. Eq. (11) becomes the well known expression: $\Delta\Phi = \frac{3}{2}aE$. For axisymmetric cells $a=b$. The symmetry axis is c . For such spheroidal cells limited in shape by an infinitely thin disk and an infinitely long cylinder, respectively, the shape dependence can be sufficiently good described by

$$\Delta\Phi = \frac{a+2c}{a+c} aE \quad (12)$$

and

$$\Delta\Phi = \frac{a+2c}{2}E \quad (13)$$

for a field oriented in a -direction and c -direction, respectively. At higher frequencies, the membrane impedance decreases by capacitive bridging. The characteristic frequency ω_c at which the induced potential is decreased by -3 dB is given by

$$\omega_c = \frac{1}{aC_m} \left(\frac{\sigma_e \sigma_i}{\sigma_e + \left(\frac{a_i}{a} - 1\right)\sigma_i} + ag \right) \quad (14)$$

σ_i , σ_e , and g stand for the specific internal and external conductivities in S/m, and the area specific membrane conductance in S/m². The complete equation for $\Delta\Phi$ at pole a of the ellipsoidal cell is

$$\Delta\Phi = \frac{a_i}{\left(1 + ag \left(\frac{1}{\sigma_i} + \frac{a_i - 1}{\sigma_e}\right)\right) \sqrt{1 + \frac{\omega^2}{\omega_c^2}}} E \quad (15)$$

with ω standing for the field frequency. Assuming a superposition of the $\Delta\Phi$ and the physiological $\Delta\Psi$ (see below) is the simplest way to explain the asymmetry in cell poration often found after dielectric membrane breakdown.

Absorption

An exposed system is only influenced by that part of the electromagnetic field energy that is absorbed (principle of Grotthus and Draper). For this reason, research on the impact of electromagnetic fields must focus on the mechanisms of absorption and the identification of the absorbing structures. Generally, the energy input into a given volume is described by Ohmic heating that is proportional to the square of the local field strength and the effective, specific conductivity of a certain medium. Magnetic absorption processes, also those based on quantum effects, such as on the spins of unpaired (radical-) electrons, can usually be neglected. Dispersions lead to subcellular field redistributions. Up to GHz-range frequencies, the local field distribution and thus local absorption greatly depend on the geometric structure and compartmentalization of a cell.

The local power dissipation (Ohmic heating) per volume element P/V in an AC-field is not directly proportional to the applied field but depends on the effective local field E_{eff}

$$\frac{P}{V} = \sigma E_{eff}^2 \quad (16)$$

The equation suggests that the power dissipation is described by a frequency independent specific DC-conductivity. In practice, the specific conductivity of structured media increases with frequency in correspondence to the permittivity decline given in Fig. 1.

Considerations show that the field strength in the external medium and thus absorption in the vicinity of the cell strongly depends on field frequency even for the simple single-shell geometry. The picture dramatically deviates from the classic one when assuming more realistic membrane and cytoplasmic properties based on their molecular structure. It suggests a possible role of the membrane in field absorption even at frequencies far above the membrane-dispersion frequency.

The Physiological Transmembrane Potential ($\Delta\Psi$)

Muscle activity or nerve excitation generate AC fields in the Hz and kHz ranges. The physiological transmembrane potential $\Delta\Psi$ is of special importance for this phenomenon. $\Delta\Psi$ generation is based on the special electric properties of biological membranes. $\Delta\Psi$ is defined as the difference of the potentials of the internal (index i) and external (index e) bulk media:

$$\Delta\Psi = \Psi_i - \Psi_e \quad (17)$$

Because of the surface potentials at the two membrane sides, fixed charges in the glycocalix and the dipole potentials of the lipid headgroups, the actual potential difference across the lipid phase of the membrane may strongly deviate from the $\Delta\Psi$. At specialized membranes like the thylakoid membranes of plant chloroplasts $\Delta\Psi$ may exceed -200 mV. Accordingly, the field strengths across the membrane under physiological conditions may be well above 10 MV/m. The membrane properties allow for the storage and transformation of electrochemical energy into chemical energy such as ATP, or in electrical energy as in nerve excitation or the electrical organs of fishes. $\Delta\Psi$ for resting neurons or muscle cells are in the range of -100 to -40 mV. Action potentials are typically in the range of 30 to 80 mV.

In excitable cells of vertebrate species, sodium and potassium ions are actively pumped outwardly and inwardly, respectively, leading to a roughly inverse distribution for the two ion species. In resting cells, the membrane permeability for potassium is much higher than for sodium. Consequently, $\Delta\Psi$ is determined by the potassium distribution. Since its concentration is much higher in the cytoplasm, random diffusion across the membrane via potassium channels leads to a net potassium loss and a negative charging

of the cytoplasm. Nerve cells are rich in voltage-gated ion channel proteins. The transition from resting to action potential is driven by a sequential change in the membrane permeabilities for sodium ions and potassium ions. The relations are described by the Goldman equation:

$$\Delta\Psi = \frac{RT}{F} \ln \frac{P_{\text{Cl}}a_{\text{Cl}}^i + P_{\text{K}}a_{\text{K}}^e + P_{\text{Na}}a_{\text{Na}}^e}{P_{\text{Cl}}a_{\text{Cl}}^e + P_{\text{K}}a_{\text{K}}^i + P_{\text{Na}}a_{\text{Na}}^i} \quad (18)$$

R , T , F , P , and a stand for the gas constant, the absolute temperature, the Faraday constant, permeability and ion activity, respectively. Indices i , e , Na, K, Cl designate internal and external bulk media, as well as the ion species sodium, potassium and chloride, respectively. Please note that for $P_{\text{K}} \gg P_{\text{Na}}$, P_{Cl} and $P_{\text{Na}} \gg P_{\text{K}}$, P_{Cl} , the Goldman equation reduces to the Nernst equations for potassium and sodium, respectively. A feedback loop where the local membrane field alters the ion permeabilities of voltage-gated ion channel proteins is the basis for the propagation of cell excitation, for example, along the axon of a nerve cell.

Passive Magnetic Properties of Biological Matter

In analogy to the electric field, a static magnetic field of strength H causes a magnetic induction B of

$$B = \mu\mu_0 H \quad (19)$$

where μ and μ_0 are the relative permeability of the material and the magnetic field constant, respectively. Since the permeabilities of biological matter are very close to unity, it is reasonable to list susceptibilities $X = \mu - 1$ (Table 1).

The low magnetic susceptibility is the reason for the very weak interaction of static magnetic fields with biological matter. Most biological cells and tissues are diamagnetic ($\chi < 0$). Paramagnetic ($\chi > 0$) desoxygenized red cells are an exception.

The high structuration of biological tissues and cells is reflected in their magnetic anisotropy $\Delta\chi$, which describes the difference in the magnetic susceptibilities parallel and perpendicular to characteristic biological structures. This feature is especially pronounced in lipid membranes that can even be orientated by magnetic fields at flux densities larger than 1 T.

Biogenic magnetites (Fe_3O_4 -crystals) are found in magnetostatic bacteria. The susceptibility of these ferromagnetic particles is as large as 10^6 . The particles are the major component of magnetosomes, cell organelles that are surrounded by a membrane. They enable the bacteria to orientate themselves along the vector of the geomagnetic field. To a lesser extent biogenic magnetites have also been found in different animals and even in the human brain. Nevertheless, it is still not clear as to whether magnetic fields can interfere with physiological processes in humans. The mechanisms of magnetic orientation of animals are not fully understood, either.

Generation and Effects of Magnetic Fields

Of course, all biological processes which involve charge movement generate endogenous magnetic fields. Such processes include the transmembrane transport of ions or charged compounds as well as the ion currents related to signal transduction in nerves and muscles. The displacement of ions and charged particles in the blood stream or the lymphatic system induces streaming potentials and in turn electric currents. Nevertheless, in no case does the induced magnetic flux densities exceed the pT-range (compare to 20–70 μT of the geomagnetic field). Currently, no hard experimental data is available on the coupling of external with endogeneous magnetic fields, subsequently influencing biologically relevant processes.

Exogenous low-frequency magnetic fields can induce electrical (eddy-) currents. Nevertheless, for effective induction, structures larger than single cells are required. Candidate structures are, therefore, the blood system and cells that are interconnected via gap

Table 1 Magnetic susceptibility of different matter

Material	$\chi/10^{-6}$
Air	0.264
Water	−9.04
Arterial blood	−9.3
Oxygenized red cells	−9.03
Desoxygenized red cells	3.88
Venous blood	−7.8
Lungs (air-filled to 15%)	−4.2
Muscle	−9.03
Liver	−8.26
Bone	−10
Biogenic Fe_3O_4 -crystals	10^{12}

junctions, allowing for the formation of large induction loops. It can be estimated, that a flux density of at least 1 mT is necessary to effect biological functions of the brain or of the heart. Static and low-frequency fields may deflect moving charges by Lorentz's force. However, ions and charged compounds can only be significantly influenced at flux densities higher than 10^6 T. Nevertheless, in larger structures such as nerves or blood vessels crossing magnetic field lines, current induction may cause nerve excitations already at flux density exceeding 10 mT.

Magnetic fields can influence the spins of unpaired electrons, for example, of organic label molecules, and nuclei with a spin different from zero, for example, of hydrogen. To orientate the spins, typically static magnetic fields of 50 mT to 6 T and 340 mT to 1.25 T are applied in Nuclear Magnetic Resonance (NMR) for medical diagnostics (usually designated as Magnetic Resonance Tomography (MRT)) and Electron Spin Resonance (ESR), respectively. The field introduces an energy difference for the two possible spin orientations. The transition from the low-energy orientation to the higher one can be induced by resonant absorption of a radio-frequency field in the MHz to GHz ranges with a frequency corresponding to the energy difference of the two spin orientations. Either the absorption or the emission of the radio frequency field induced by the relaxation of the spin distribution is detected in the methods.

Static and low-frequency magnetic fields have been shown to influence chemical reactions which involve radical-pair intermediate states in electron transfer processes. The lifetime of triplet-singlet interconversions in such reactions have been altered at magnetic flux densities of 1 mT and beyond. This mechanism may as well apply to biochemical reactions. For the interaction of magnetic fields with biological processes, other mechanisms such as cyclotron resonance in protein channels and ion parametric resonance in macromolecules have also been proposed, but could not be verified so far.

Introduction

Research on biological and health effects of electromagnetic fields (EMFs) has been driven in the last few decades by public concerns about their potential detrimental effects. Up to date, an extensive application of EMFs, for both diagnostic and therapeutic purpose, has taken hold as well, moving the attention from the sole aspect of health protection.

EMFs sources are broadly diffused in the environment, varying both in emission intensity and frequency range (see [Figure 1](#) for EM spectrum visualization). Static fields (SF at 0 frequency or namely DC, see [Figure 1](#)) are naturally associated to the earth surface, weather changes, and solar activity. Nonnaturally derived fields come from household and office appliances, video displays, power transmission lines, industrial processes, and medical and research applications (Magnetic Resonance Imaging, MRI).

High voltage lines and all the electric devices are also the principal sources of extremely low frequency fields (ELF, <300 Hz, see [Figure 1](#)), operating at 50 Hz (Europe) or 60 Hz (America), commonly present in our daily life. Within particular occupational situations, such as industrial machines, induction ovens, or electrolytic cells, workers can be exposed to high electric or magnetic fields intensities.

Exposure to intermediate frequency (IF, 300 Hz < $f \leq 10$ kHz, see [Figure 1](#)) fields has been so far limited to specific situations, but emerging technologies, such as anti-theft devices, badge readers, induction hotplates, or fluorescent bulbs, producing IF emissions, are now amply diffused.

In the radiofrequency (RF, 10 kHz < $f \leq 300$ GHz, see [Figure 1](#)) range, natural sources are essentially represented by electrical discharges in the atmosphere and solar and cosmic radiation. Human exposure, along with domestic and indoor transmitters, lay essentially on portable wireless telecommunication systems; mobile phones remain the main source of exposure for brain tissues. RF EMF levels are not going to rise, having new technologies, like digital broadcasting, reduced EMF exposure from far field sources (radio and TV broadcasting and mobile phones base stations). The current tendency is to make use of devices at close contact with human body but of lower emissions, working at higher frequencies than GSM.

This classification does not rule out the fact that in real life the EMF exposure is often due to multiple sources acting contemporaneously at different frequencies. However, few available studies on combined exposure to EMF of different frequency ranges have been carried out and they do not provide sufficient information to challenge existing risk assessment; in addition, in most experiments an absence of effects has been reported.

[☆]*Change History:* February 2015. C. Marino, P. Galloni, and C. Merla replaced Table 1 with [Figure 1](#). Several new sections have been added to the original version to make the article up to date. In the Further reading section, several references have been added to the former list.

Figure 1 Scheme of non-ionizing and ionizing spectrum of radiations. Some sources of radiation are also sketched.

Another important issue is the combination of EMF exposure with other physical (e.g., ultrasound and ionizing radiation) or chemical agents. However, the reports on combined effects lack consistency and are not linked to specific experimental conditions. Therefore, further research is needed in order to clarify any relevance of combined exposures, especially to human cancer risk under real life exposure situations, and to explore the potentially beneficial (protective) effects of such exposures. In next paragraphs brief indication will be given also on these aspects when available.

Explicit distinctions must be made between the concepts of interaction, biological effect, and health hazard, consistent with the criteria used by international bodies when making health assessments: biological effects occur when fields interact to produce responses that may or may not be experienced by people. Deciding whether biological changes have health consequences depends, in part, on whether they are reversible, are within the range for which the body has effective compensation mechanisms, or are likely, taking into account the variability of response among individuals, to lead to unfavorable changes in health. World health organization (WHO) defines health as the state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity. Not all biological effects are hazardous: some may be innocuously within the normal range of biological variation and physiological compensation. Others may be beneficial under certain conditions, and the health implications of others may be simply indeterminate. In this document a health hazard is defined as a biological effect outside the normal range of physiological compensation and adverse to well-being.

It is known that EM interference with electromedical devices, such as cardiac pacemakers, leads to adverse health consequences, but this review is only concerned with direct effects of EMFs on living tissues.

The scientific approaches to health risk assessment related to non-ionizing EMFs are the same as in the ionizing range and toxicology in general, i.e., epidemiology, experimental studies on humans, animals, and cells in culture.

Many effects on biological systems exposed to EM fields have been reported. In the last 30 years, numerous experiments have been performed in laboratories worldwide to assess the biological effects of EM fields. This has led to the design and building of several types of exposure systems for *in vitro*, *in vivo*, and human studies. The goal is to expose the biological samples (mainly cell cultures and animals) to well-characterized fields under well-defined environmental conditions. Indeed, it is now internationally recognized that exposure setups have to be of sufficient quality to warrant that biological findings were not due to physical artifacts. Exposure setups, further, have to guarantee suitable arrangements for blind sham (i.e., without EM field) exposures. There have been many improvements in the design of exposure systems in recent years and most of the key parameters described below are well-characterized and controlled. However, standardization of these systems has only been achieved within some of the multi-center research programmes.

This article gives a review of the existing scientific knowledge on the biological and health effects of EMFs for the most part in the two main frequency ranges of concern: ELF and RF. A brief section will be devoted to the other frequency intervals as SF and IF sources for which only limited studies are up to now available.

Bioeffects of Static Fields

SF interact with moving charged particles, such as ions, and with magnetic moments arising from the orbital motions of electrons in atoms. SF can interact with paramagnetic elements in the body (metals and molecules as hemoglobin or ferritin) and modify

chemical reaction rates. Most of the tissues in the body can conduct electricity, but in ordinary conditions currents flow only in particular tissues, as to say nerves, muscles, and excitable cells. Eddy currents can be induced by external SF if the biological tissue is moving in relation to the field, for example for body movements or blood flow. Manifest effects of interaction with SF are reported, including peripheral nerve stimulation, perturbation of the vestibular system (dizziness), magnetophosphenes, or metallic taste, but are often related to high levels of exposure (over 2–8 T to evoke vertigo and other sensory perceptions or peripheral nerve stimulations respectively).

Cellular Models

Strong SF (>0.2 T) have been tested in different *in vitro* systems for various exposure durations, evidencing that magnetic fields can orientate both cells and macromolecules. Genotoxic potential has been evaluated failing to show effects, while gene expression was reported to be up-regulated in different investigations. An increased sensitivity to harmful agents was reported in studies of combined exposure.

Animal Models

Cancer-related endpoints, reproduction, development, physiological, and behavioral responses have been studied after SF exposure *in vivo*. Concerning carcinogenicity, long-term investigations were performed only with relatively weak SF, drawing inconclusive results. Few high-quality studies with low intensity SF (<1 T) on fertility, growth, and development have been performed, showing no consistent adverse effects. Some effects were reported for studies on the cardiovascular system (evidencing, for example, generation of electric potentials across arteries), but their physiological consequences are unsure. Publications from a single laboratory evidenced behavioral and neural changes (i.e., vestibular disorder) for exposure above 4–7 T.

Human Studies

Epidemiological investigation, trials, and case-report studies do not suggest long-term adverse health effects due to SF exposure. A small evidence of increase in leukemia risk in electrolytic plants workers was reported. Only limited evidence exists (only one study) for an increase of metallic taste or vertigo in people working in MRI facilities.

Bioeffects of ELF Fields

In view of the interaction processes of fields with biological organisms (mainly induced electric fields at ELF), the effects of external magnetic fields, which penetrate the body, have been the main focus of the research projects. In contrast, external electric fields at ELF do not penetrate well the organism because of its conductivity. This is not true for direct stimulation of nerves and other excitable cells using electrodes. Electric fields (mainly E pulses of μ s up to ms in duration) can also induce polarization of the cell membranes leading to specific effects such as electroporation.

Many mechanisms have been proposed through which living systems could interact with electric and magnetic fields at low frequencies. However, both laboratory studies and controlled human studies have provided evidence mainly for electrically-based phenomena that occur in the presence of ELF fields and that are present only during exposure to these fields. However, a great interest in direct magnetic field effects on biochemical reactions has recently undergone a further increase because of very accurate experimental evidences associated with avian magneto-reception involving Cryptochromes. These studies suggest the involvement of a radical pair in the reaction cascade and, hence, the plausible role of direct magnetic field effects.

Induced electric signals in tissues of the nervous and visual system of animals exposed to ELF electric and magnetic fields can produce effects that lead to field perception. The most notable effect that occurs in humans exposed to fields of moderate intensity is the induction of visual phosphenes. The neuronal circuits of the retina form a part of the CNS and thus the magneto-phosphene threshold may be taken as a realistic indicator of the threshold value for functional changes induced in other parts of the CNS. Threshold values at 20 Hz were estimated at approximately 100 mV m^{-1} . Direct effects on the peripheral nervous system occur only at relatively high levels of electrical stimulation (about 2 V m^{-1} and with increasing thresholds for frequencies above 1 kHz).

A variety of other potential mechanisms for interaction of ELF electric and magnetic fields with living systems have been proposed, but not demonstrated to produce effects that could significantly perturb normal biological functions. Examples of such interactions are the following: (1) magneto-chemical interactions with charge-transfer reactions which do not appear to influence biochemical pathways such as those involving electron transport; and (2) resonance interactions involving combined static and ELF fields in specific geometric configurations have not been shown to have significant biological effects, consistent with predictions based on well-founded physical arguments.

Cellular Models

There is a large and varied body of research literature on the ability of fields to cause changes in cellular models. *In vitro* studies were extensively performed and published up to 2000. More recent results suggest that, overall, the evidence for stimulation of cell division by ELF fields is at best equivocal. Neither is there clear evidence that ELF magnetic fields can alter calcium ion homeostasis.

Finally, the data on several aspects of intracellular signaling do not consistently support the existence of field effects on these signaling pathways. Furthermore, the types of effects reported, when found, have been of a magnitude that gives little support to the conclusion that they are of consequence for human health.

Redox-related mechanisms have been mainly documented for ELF, studies proposed that exposure can stabilize free radicals increasing their lifetime and allowing a wider dispersion rather than their return to the basal level. Super oxide production in mouse macrophage was also detected after ELF exposure in a dose-dependent manner. Thus considering evidence from various authors, it seems plausible that reactive oxygen species (ROS) generation could be well-considered as an *in vitro* model for interaction between ELF and biological systems.

Animal Models

Overall, a large number of studies have been carried out, testing many different biological endpoints in a variety of animal species.

With regard to genotoxicity, there is no clear evidence that exposure to ELF magnetic fields presents a hazard. Relatively few animal studies have been carried out, however, and the subject has been more extensively investigated at the cellular level (see above). Similarly, no convincing evidence has been found from experimental studies supporting the hypothesis that exposure to power-frequency magnetic fields increases the risk of cancer.

Many studies have dealt with the reproductive and developmental effects of exposure to power frequency electric and magnetic field effects and VLF visual-display-frequency magnetic fields using chicks and mammalian species. Overall, the data do not support the hypothesis that low-frequency EMF exposures result in reproductive toxicity.

Generally, the evidence for an effect of exposure to power-frequency EMFs on melatonin levels and melatonin-dependent reproductive status is mostly negative in seasonally-breeding animals. In addition, no convincing effect on melatonin levels has been seen in a study of non-human primates chronically exposed to power-frequency EMFs. The interpretation of the outcome of studies on rat pineal and serum melatonin levels was more problematic: both positive and negative effects were reported in studies without apparent technical or analytical deficits.

With regard to possible effects on other hormones, with the possible exception of transient stress following the onset of ELF electric field exposure at levels significantly above perception thresholds, no consistent effects have been observed in levels of the stress-related hormones of the pituitary–adrenal axis, growth hormone levels, levels of hormones involved in controlling metabolic activity or those associated with the control of reproduction and sexual development. Results of these studies are inconsistent and contradictory, reporting no effects or either an increase or a decrease of the normal hormones concentration. There is little consistent evidence of any inhibitory effect of ELF EMF exposure on various aspects of immune system function including those relevant to cancer. In addition, there was no compelling evidence that hematological variables were affected by exposure to ELF fields.

In general, many studies of nervous system functions were either negative, or difficult to interpret because of weakness in experimental design or confounding by artifact. However, several studies suggest possible EMF effects on the opioid and cholinergic systems, along with concomitant changes in analgesia and in the acquisition and performance of spatial memory tasks. Effects on opioid and cholinergic systems should thus be further investigated.

Action of free radicals in brain under ELF exposure was fully analyzed in a recent review evidencing, in particular, redox and trophic responses in mouse brain and brain lipid oxidative damage. Moreover, antioxidant defense can be specifically deteriorated by ELF exposure thus amplifying oxidative stress both in young and aged rat brain. However, a direct link to health risk assessment of these results is difficult due to the limited number of conducted studies.

Hypotheses relating ELF to neurodegenerative diseases are a relatively novel part of the EMF research area and, so far, only a modest number of studies have been performed if compared to cancer research field. A single study on animals, genetically modified rodents for amyotrophic lateral sclerosis (ALS), was performed to assess the possible effects of chronic exposure to ELF on the development of this neurodegenerative disease. Authors did not reveal any difference between exposed and control animals, providing no evidence of a link between ELF and ALS in an oxidative prone experimental model. Connection with Huntington's disease (HD) was also investigated *in vivo*. These data together other observations seem to support the hypothesis of a neuro-protective effect elicited by ELF on HD.

The potential sensitivity of people with epilepsy to EMF exposure is an important factor that should be considered. Exposure of animals to EMFs before testing has been reported to have an inhibitory effect on subsequent tests of epileptic-seizure sensitivity but the type of response was not consistent among different studies. Further investigation should be carried out of possible effects during exposure.

Moreover, ELF seems related to the offset and onset of evoked potentials, this suggests that the field was transduced like ordinary stimuli such as light and sound. However, the changes induced by ELF were governed by nonlinear and complex law for which the underlying mechanism still remains unknown.

There is convincing evidence that ELF electric fields can be perceived by animals, most likely as a result of surface charge effects; threshold values for both rats and baboons lie between about 5 and 15 kV m⁻¹. Exposures above these thresholds are sufficient to be mildly aversive and will result in transient arousal but mostly disappear following prolonged exposure.

Largely consistent with earlier results, recent studies have reported that exposure to magnetic fields has no effect on activity or locomotion, but may affect the performance of spatial memory tasks (both deficits and improvements have been reported) and engender subtle increases in behavioral anxiety and stress. Other studies have investigated potential molecular and cellular

mechanisms, and despite a number of studies continuing to report candidate mechanisms, particularly regarding effects on ROS, none that operate at levels of exposure found in the everyday environment has been firmly identified.

Human Studies

Small inconsistent changes have been described in circulating levels of leukocytes, but as with animals, the relevance to human health of these changes is not clear. No indication of a clear-cut cytogenetic effect was observed in the blood cells of exposed subjects. The circulating hormone levels in humans, including melatonin, are not adversely affected by exposure to power-frequency electric and/or magnetic fields. At the same time, two recent independent studies have examined the effects of occupational exposure to magnetic fields by examining peripheral blood of exposed workers. At best, these provide only weak evidence for a field-related effect on natural killer cell activity and antioxidant activity.

Positive results from studies on the power spectrum of different EEG frequency bands and on sleep structure have been performed at occupational exposure levels higher than general environmental levels.

In the light of cognitive and performance studies that show a large number of positive biological effects the need for further studies is warranted in order to clarify their significance for human health.

Some authors investigated the possible effects of fields generated by electric motors in incubators on autonomic function in newborn babies. Transient changes in the total power and spectral components of heart rate variability (HRV) were noted when the motors were running. Confirmatory studies are required to determine the significance of this observation. Others reported that HRV in adults was affected by exposure to very weak fields (around 2 μT). The direction of change was dependent on the frequency used. The majority of published cardiovascular changes stay within the range of normal biological variations; else, the study protocols and the results have not been successfully replicated in other laboratories.

More recently, it has been hypothesized that exposure to low frequency fields is associated with several neurodegenerative diseases. For Alzheimer's disease (AD) and ALS more studies have been published, while lack of data and inconsistency emerged for diseases as Parkinson (PD). Some of these reports concerning Alzheimer and ALS suggest that people employed in electrical occupations might have an increased risk. So far, no biological mechanism has been established which can explain this association, although it could have arisen because of confounders related to electrical occupations, such as electric shocks. However more sophisticated studies do not observed increasing of the risk. Hence, overall the evidence for the association between low frequency exposure and AD and ALS is inconclusive.

Only few new studies have been published since the previous opinion and they do not provide support to increase the risk for AD.

As perception of electric or magnetic fields has been reasonably well characterized, skin symptoms, headache, and mood disturbance claimed by working near computer screens or in proximity of other environmental ELF sources have not reliably been linked to any electromagnetic exposure produced by these devices. Also, reported studies do not indicate any ability of individuals who alleged electromagnetic hypersensitivity to react to any test-field situation, suggesting that other environmental or psycho-social factors should be considered for people suffering from this pathology.

Conclusion

There is today little scientific evidence suggesting that ELF EMF exposures pose a health risk. The strongest evidence for health effects comes from an association observed with childhood leukemia. In contrast, mechanistic studies and animal toxicology data fail to demonstrate any consistent pattern across studies, although sporadic findings of biological effects (including increased cancers in animals) have been reported.

This was at the basis of a classification performed by the International Agency for Research on Cancer in 2001, ranking ELF magnetic fields as possibly carcinogenic to humans (Group 2B) (IARC, 2002). The classifications essentially were based on the facts that epidemiological studies showed a consistent association between magnetic fields above approximately 0.3/0.4 μT and a doubling in risk for childhood leukemia, although chance, bias and confounding could not be ruled out as an explanation with reasonable confidence, but that experimental studies or mechanistic modeling provided little support for, or explanation of, these findings.

The lack of connection between human and experimental data (animal and mechanistic) severely complicates the interpretation of these results.

Bioeffects of IF Fields

For the purposes of risk assessment, IF fields have only been considered as a separate entity relatively recently. Largely depending on the definition of their frequency range, IF fields have been considered in various reviews and monographs alongside either low or high frequency fields. IF fields can induce electric fields and currents in the human body, much as it is seen with low frequency fields, but they can also induce heating effects in the body as in high frequency field exposures. Assessments of possible hazards at IF are based primarily on extrapolation from data on exposure to higher and lower frequencies. Very little useful epidemiological data

are available. The existing evidence largely comes from older studies that tended to use job title as a surrogate for exposure. Groups studied include users of visual display units (VDUs) associated with personal computers and radio and telegraph operators. Outcomes studied included cancer as well as effects on the eye, the cardiovascular system and the reproductive system. Although no particular risks were identified, the quality of existing studies is limited. There have been some animal studies exploring the effects of IF fields from VDUs, particularly on reproduction and development. There are fewer studies on humans, although some studies have investigated effects of IF fields on skin. With the demise of cathode-ray based monitors, more recent work exploring health risks associated with computer use in humans has concentrated on ergonomic issues (and is not considered here). Despite some limited evidence from animal studies that have reported field-dependent effects on reproduction and development, there is no consistent or conclusive evidence of field-dependent adverse effects. Overall, it can be concluded that there was insufficient data for a health risk assessment, so the overall evaluation for all health endpoints has to be considered to be inadequate. Since then, an IARC Working Group has classified EMFs with a frequency range of 30 kHz to 300 GHz as being 'possibly carcinogenic to humans' (see Section 5).

Cellular Models

In vitro IF exposure of a single work on genotoxicity gives negative results as well as stress responses on glioblastoma cells. Negative effects were also obtained for global gene expression on human astroglia cell line.

Animal Models

A series of study of IF exposure effects on embryonic development was carried out recently with negative outcomes. Globally, no effects on reproductive outcome were documented in these studies.

Bioeffects of RF Fields

Concerns about health effects caused by exposure to RF are mainly related to mobile telephones and base stations, becoming a major societal issue in some countries, or at least among part of the population. Mobile (or cellular) telephony has developed very rapidly, followed and unseated in the last years by phones equipped for data services (smart phones, 3G). They are now part of the basic equipment of modern life and billions of such devices are in use worldwide. Stories about health risks from radiofrequency radiation (RFR) from mobile phones and base stations have become common in the media over the past 10 years.

Several systems are used in mobile telephony worldwide, all based on the same principle, i.e., 'cellular' mapping of the territory. In each cell, a base station (BTS) emits toward and receives signals from the mobile telephones active in that cell (up to around 50). There are, for example, 30 000 BTS in France used by three networks. The carrier frequency varies from 400 to 2100 MHz and the voice or data information is coded digitally either by frequency or phase modulation. Mobile telephones are two-way radio transmitters operating in the 400–2100 MHz frequency range. In the GSM system, for example, the peak power emitted is 2 W, but the time-averaged power is always below 1/8 of this value, as power control reduces emission to the lowest level required. About half of the emitted power is absorbed by the user's head, i.e., a maximum of 125 mW. Power absorption is expressed as specific absorption rate (SAR) in W kg^{-1} . New generation of smart phones include contemporarily a large number of communication protocols as GSM/GPRS/EDGE/UMTS/HSDPA/HSUPA/LTE spanning up to frequencies above 2450 MHz.

Major improvements have been achieved in measuring the SAR in liquid phantoms and calculating power distribution in the head using numerical phantoms over the last 10 years. Today, the worst-case SAR associated with the average GSM phone on the market is ca. 0.5 W kg^{-1} , i.e., 1/4 of the recommended local-exposure limit value. It is now known with certainty that temperature increases in the brain periphery caused by the waves emitted by mobile telephones does not exceed 0.1°C . As for smart phones, they are backward-compatible with older mobile phones networks, and usually operates with lower emissions than their precursors.

As a result of current changes in usage – increasing use of text and image messages and hands-free kits – mobile telephones are less frequently placed against the ear. This dramatically reduces exposure of the tissues in the head.

GSM base-station antennas have an emitting power of ca. 20 W. They are usually placed on rooftops and the emission beam is disc-shaped. Maximum exposure occurs on the ground, approximately 200 m from the BTS and it is almost zero at the bottom of the building or mast on which the antenna is mounted. Exposure of the public to the RFR emitted by base stations is typically 1/10 000 of the recommended limit in terms of incident power. There is a consensus in the scientific community that base stations do not represent a health hazard.

There is much scientific evidence, based on existing research, that warrants limiting exposure to high-level RFR due to the 'thermal effects' caused by heating of the tissues at SAR levels that correspond to a temperature elevation of a few degrees. However, this does not occur with mobile telephones. The search is thus for 'non-thermal' effects and most of the research activity has been aimed at defining the thresholds for these effects, with respect to existing exposure guidelines based on acute effects known to be due to heating.

Health risk assessment associated with RF benefits from a database spanning over 50 years: the WHO and IEEE databases list about 2000 peer-reviewed publications, from biophysical theoretical analyses to human epidemiological studies. The EHC

(Environmental Health criteria) Monograph by WHO, peer-reviewing all the literature on this subject from year 2000 is periodically realized.

The carcinogenicity of RF EMFs was assessed by a working group at IARC (International Agency for Research on Cancer), classifying them as ‘possibly carcinogenic to humans (Group 2B),’ after the examination of the relevant human, animal and cellular studies, mainly due to limited epidemiological evidence. A causal link between RF exposure and increased risk of cancer was considered possible, but chance, bias or confounding factors could not be excluded.

Cellular Models

A number of replication studies that addressed some positive findings on enzyme activity, gene expression, and DNA alteration have all proven negative so far. A wide range of short-term, low-level *in vitro* experiments have shown that exposure did not cause cell death, implying that RF is not a toxic agent. Furthermore, the weight of evidence available today (induction of DNA strand breaks, chromosome aberrations, micronuclei formation, DNA repair synthesis, sister chromatid exchange, and phenotypic mutation) supports the conclusion that RF is not genotoxic. However, the synergy of RF with chemical agents or other physical agents still needs further investigation.

Weak evidence is reported that RFR activates a stress response or production of ROS (free radicals) in human and animal cells under non-thermal conditions. The same outcome was evidenced about HSP (Heat Shock Proteins) production, cell proliferation, or apoptosis.

A few studies reported positive findings, often reversible, and linked to critical physical exposure parameters such as modulation, frequency and power ‘windows,’ field polarization, or background ELF fields.

Animal Models

A large number of animal experiments have been performed over the past 50 years, using various frequencies and modulations. It is clear from these data that the vast majority of the reported biological effects are due to heating. These effects result either from a rise in tissue or body temperature exceeding 1 ° C or in physiological and behavioral responses aimed at minimizing the total heat load.

Major improvements in exposure system design have made it possible to better characterize the SAR within the organism, and allow for either local exposure that mimics mobile telephone use (e.g., loop antenna, carousel) or whole-body exposure related to base-stations (e.g., Ferry’s wheel, reverberation chamber, circular waveguide).

Results on most of the non-cancer endpoints have been negative (memory, EEG, hearing, etc.) except for data on the permeability of the blood–brain barrier, which was found to be increased by two research groups but not by several others.

Therefore, most of the major ongoing studies deal with cancer models. All of the long-term bioassays or sensitized studies have given negative results except for one using transgenic mice, genetically modified to increase the background incidence of lymphomas; an increased tumor incidence was found following GSM exposure. Most of more recent studies have not produced any persuasive evidence that RF fields are carcinogenic, even if a long-term low-level GSM exposure was reported to shorten life-span in rats, and increased lung tumor development was showed in mice co-treated with UMTS fields and chemical carcinogens during gestation and after weaning, such studies requiring confirmation. A large NTP (National Toxicology Program) study is ongoing, and unresolved questions about studies design and interpretation of results should be clarified through this study.

A number of studies on animals ranging from focus on learning and memory, on behavior, biochemical brain responses, sensory organs, neurogenesis, and cytotoxicity, to neurodegenerative diseases have been carried out. Different endpoints have been studied at various SAR-levels in both mice and rats. The few positive findings appears inconsistent and mostly at levels well above guideline values.

Since the issue that children are more sensitive than adults to the wireless telephones associated emissions has recently set in, important and well designed investigations of RF effects on pregnancy outcome, development of the offspring, and immunological parameters have been performed in the last years. Although one study suggested an association between early postnatal exposure and accelerated maturity in male rats, the evidence does not indicate that prenatal or early postnatal exposures are linked to acute adverse responses or the development of long-term harmful changes.

Human Studies

In spite of the obvious limitations of human experiments in terms of endpoints and exposure characterization, several investigations have been performed using various models. Findings have either been negative or difficult to replicate (sleep, EEG, cognitive functions, etc.).

No unequivocal increased risk of brain tumors, head and neck tumors, or other malignant diseases has been indicated by epidemiological studies on RF EMF exposure. Great interest regarding an increased risk of glioma and acoustic neuroma in heavy users (corresponding, as in the IARC 2013 Monograph, to half an hour of daily use over years or more) of mobile phones derived from early studies. Based on the most recent cohort and incidence time trend studies, it appears that the evidence for an increased risk of glioma became weaker while the possibility of an association with acoustic neuroma remains open.

Inconsistent results have been showed by neuro-physiological studies on possible effects on brain function in humans, including macrostructure of sleep, electroencephalography (EEG), event-related potentials, slow brain potentials, cognition, as well as

regional blood flow and oxygenation changes. Although the associated biological mechanism and significance are still unclear, the former evidence that RF exposure may affect brain activities, as for EEG studies during wake and sleep state, is further supported by more recent studies. Overall, there is evidence that exposure to RF fields does not cause symptoms or affect cognitive function in humans.

Clearly, the main issue today is the potential greater sensitivity of children to mobile phone emissions. Their lifetime exposure, the fact that their CNS is still developing, and, possibly, increased RF absorption in the head, have led to concerns that cannot be easily resolved through laboratory investigations and numerical modeling. A large Danish study has reported results that suggest higher prevalence of some behavioral and health disorders in children. About that, some considerations must be taken into account: results are not confirmed in other studies; some methodological weaknesses are present; the exposure indicators such as frequency of mother's mobile phone use could not at all be relevant for fetal exposure *in utero*; attention deficit disorders have a clear hereditary component. By and large, the evidence for an association between behavioral disorders and RF exposure of the fetus is considered weak.

Few studies have investigated the possibility that exposure to low-level RF fields from mobile phones and other sources can affect male fertility, but none of the recent studies are particularly informative.

Conclusion

RFR can cause biological effects when exposure is sufficiently intense: possible injuries include cataracts, skin burns, deep burns, heat exhaustion, and heat stroke. They are mostly due to heating. There have been scattered reports of effects that do not appear to be due to temperature elevation: the 'non-thermal' effects. None of these effects have been independently replicated, and most have no obvious consequence to human health. Furthermore, there are no known biophysical mechanisms that suggest that such effects could occur.

Following the very rapid development of mobile telephony, a major research effort has been carried out worldwide (tens of millions of euros per year). Europe is most active (UK, Germany, Italy, and Finland, in particular), but many research groups are contributing from Japan, US, and Australasia.

Most governments have addressed the issue of mobile telephony and health and several international and national expert committees have written accurate summaries of current knowledge (see the list of the most recent reports in the 'Further reading' section). Their conclusions converge toward an absence of health effects related to mobile telephones, but all encourage continuing research in some areas.

In answer to the question: 'mobile telephony: is there evidence of harm?' one must conclude that the weight of scientific evidence does not support health concerns or indicate any health risk from mobile phones in normal use, nor that there is any accepted mechanism for potential health effects at the low levels associated with these devices. Findings to date, including epidemiological studies and laboratory studies of animals exposed both short-term and for their entire lifetimes, have not provided evidence that exposure causes cancer, or affects biological tissues in a manner that might lead to, or augment, any disease. However, some pending issues as the potentially greater sensitivity of children has been addressed using *in vivo* models as well as epidemiological investigations also still ongoing.

Medical Applications

Recently the therapeutic use of EMF in various medical applications has raised much attention within the scientific community.

The deep description of the effects and application of EMF in this area of research and clinics is beyond the scope of this article, even if some fundamental effect, as the ones related to RF or MW heating, nervous system stimulation and electrical membrane polarization to induced electroporation has been also previously discussed.

Occupational Exposures

Directive 2013/35/UE of June 26, 2013 on the minimum health and safety requirements regarding the exposure of workers to the risks arising from physical agents (EMFs) covers all known direct biophysical effects and other indirect effects caused by EMFs. However, the Directive currently only addresses short-term effects and does not concern possible long-term effects.

Health Risk Assessment

The process of health risk assessment by bodies such as ICNIRP (International Commission on Non-ionizing Radiation Protection), IEEE (Institute of Electrical and Electronics Engineers), IARC (International Agency for Research on Cancer), and WHO relies heavily on judging the quality of investigations. As stated above, the quality of exposure systems has greatly improved and can now be considered adequate. The use of well-grounded experimental protocols (sham-exposure, blinding of exposure and biological tests,

positive controls) has become generalized. Moreover, it is now common practice in the field of bioelectromagnetics to ascertain that any positive results are replicated in at least one independent laboratory. In spite of these improvements, it should be noted that only a few top-level biology laboratories have engaged in this type of research, partly due to interferences created by societal and media pressure.

Within its EMF International Programme, WHO has reviewed the science and issued research recommendations. The main conclusion from these reviews is that EMF exposures below the limits recommended in the ICNIRP guidelines do not appear to have any known impact on health. However, there are still some key gaps in knowledge requiring further research to provide definitive health risk assessments are provided by the World Health Organization within the EMF Project and published into a dedicated Research Agenda.

Remaining uncertainties in the science database have led to pressure to introduce precautionary measures until gaps in knowledge are filled. If precautionary measures are introduced to reduce RFR levels, it is recommended that they should be voluntary and that health-based exposure limits be mandated to protect public health.

Nomenclature

B_0	magnetic induction ($\text{kg A}^{-1} \text{s}^{-2}$)
$E_{S,MS}$	Zeeman energy of the level ($\text{kg m}^2 \text{s}^{-1}$)
g_e	electron g factor
$\hbar$	Planck constant $h/2\pi$ ($\text{kg m}^2 \text{s}^{-1} \text{rad}^{-1}$)
H_0	external magnetic field (A m^{-1})
I	nuclear spin angular momentum
1J	coupling constant (s^{-1})
k	Boltzmann constant ($\text{kg m}^2 \text{s}^{-1} \text{K}^{-1}$)
M	magnetization (A m^{-1})
M_S	one-electron spin angular momentum quantum number
N_A	Avogadro constant (mol^{-1})
r	distance (m)
$R_{1\text{dia}}$	diamagnetic contribution to the longitudinal relaxation rate (s^{-1})
$R_{2\text{dia}}$	diamagnetic contribution to the transverse relaxation rate (s^{-1})
R_{1M}	paramagnetic contribution to the longitudinal relaxation rate (s^{-1})
R_{2M}	paramagnetic contribution to the transverse relaxation rate (s^{-1})
S	electron spin angular momentum
S	orientation tensor
T	temperature (K)
V_M	molar volume ($\text{m}^3 \text{mol}^{-1}$)
γ_I	nuclear magnetogyric ratio ($\text{rad kg A}^{-1} \text{s}^{-3}$)
δ	chemical shift
$\Delta\nu$	line width (Hz)
$\Delta\chi_{\text{ax}}$	axial magnetic susceptibility anisotropy (m^3)
$\Delta\chi_{\text{rh}}$	rhombic magnetic susceptibility anisotropy (m^3)
μ	magnetic moment (A m^2)
μ_0	permeability of a vacuum ($\text{kg m s}^{-2} \text{A}^{-2}$)
μ_B	electron Bohr magneton (A m^2)
$\rho_{I(J)}$	contribution to longitudinal relaxation of nucleus I due to the coupling with nucleus J (s^{-1})
σ	dipolar shielding tensor

[☆]Change History: June 2015. G. Parigi made a few minor changes in the previous text. Two new sections: 'Recovering Information on Structure Heterogeneity' and 'Tagging of Diamagnetic Proteins' were added and references have been changed.

τ_c	correlation time (s)
τ_M	exchange time (s)
τ_r	reorientational time (s)
τ_s	electron relaxation time (s)
χ	magnetic susceptibility per molecule (m^3)
χ_v	susceptibility per unit volume
ω_I	nuclear Larmor frequency (rad s^{-1})
ω_S	electron Larmor frequency (rad s^{-1})

Introduction

Nearly half of proteins in all living organisms contain a metal ion. Such metalloproteins may be diamagnetic or paramagnetic systems, depending on the nature of the metal ion and its spin state. The presence of a diamagnetic metal ion in the protein does not affect the NMR parameters appreciably, and the usual techniques for protein solution structure determination can be applied, with the additional problem of locating the metal ion. On the contrary, the presence of a paramagnetic metal ion largely perturbs the NMR parameters, as it affects both the signal line widths and the intensity of the Nuclear Overhauser Effects (NOEs). In fact, since the magnetic moment of an unpaired electron is 658.2 times larger than that of proton, the major magnetic interaction of any nucleus not far from the metal ion will be provided by the dipolar coupling with the unpaired electron rather than with other closer nuclei (Figure 1). Such interaction sizably increases both their longitudinal and transverse relaxation rates – two parameters strongly affecting the protein NMR spectra.

If R_{1M} and R_{2M} indicate the paramagnetic contributions to the longitudinal and transverse relaxation rates, respectively, the increase in nuclear signal line width due to the presence of a paramagnetic metal ion will be given by

$$\Delta\nu = R_{2M}/\pi$$

and the change in NOE intensity by

$$\frac{\eta_{I(J)}^{\text{para}}}{\eta_{I(J)}^{\text{dia}}} = \frac{\rho_{I(J)} + \rho_{I(\text{other})}}{\rho_{I(J)} + \rho_{I(\text{other})} + R_{1M}}$$

where $\rho_{I(J)}$ is the contribution to longitudinal relaxation of nucleus I due to the coupling with nucleus J and $\rho_{I(\text{other})}$ includes all other contributions to relaxation of nucleus I , with the exception of the coupling with nucleus J and with the paramagnetic center, R_{1M} .

The increase in line widths and the decrease of NOE intensities make it more difficult to collect data for structure calculations. For $R_{1M} > R_{1\text{dia}}$ and $R_{2M} > R_{2\text{dia}}$ the integrals of NOESY cross-peaks decrease linearly with R_{1M} , and the scalar coupling cross-peaks decrease quadratically with R_{2M} . However, the presence of a paramagnetic metal ion makes available a new class of structural restraints: the paramagnetism-based restraints. The amount of information related to these new restraints is often able to compensate the loss of information due to the effects described above. Paramagnetism-based restraints are derived from contact shifts (CSs), pseudo-CSs (PCSs), relaxation enhancements, residual dipolar couplings (RDCs) arising from partial metalloprotein self-orientation, cross-correlation between Curie relaxation and dipole–dipole nuclear relaxation (CCR).

The availability of the paramagnetism-based restraints may also make it convenient to use a paramagnetic metal ion in the place of a native diamagnetic metal or as a probe to be attached to a protein.

Paramagnetism-based restraints have also the advantage of being often quicker to obtain than the classical NOE restraints, especially for proteins of large size. Therefore, the development of protocols for their efficient use is of great perspective importance in order to increase the speed in solving protein structures and to obtain structures of large proteins employing NMR.

Figure 1 The magnetic interaction of a nuclear magnetic moment with the electron magnetic moment can be larger than that between two close nuclei, due to the larger electron magnetic moment.

The Magnetic Susceptibility in Diamagnetic and Paramagnetic Systems

All the paramagnetism-based effects indicated above originate from the dipolar coupling between protein nuclei and the unpaired electron(s) and/or from the presence of paramagnetic susceptibility, usually an anisotropic quantity, which is now introduced.

When a molecule is immersed in an external magnetic field H_0 , an induced magnetic moment is established along H_0 . A magnetization M thus arises, defined as the induced magnetic moment per unit volume, usually proportional to H_0

$$M = \frac{\chi_V B_0}{\mu_0}$$

where μ_0 is the permeability of free space and $B_0 = \mu_0(H_0 + M) \approx \mu_0 H_0$. In systems that do not contain paramagnetic ions, χ_V is the diamagnetic susceptibility, usually independent of B_0 and is negative.

In paramagnetic systems, χ_V is dominated by the paramagnetic susceptibility per unit volume, it is independent of B_0 and is positive. An average induced magnetic moment per particle, $\langle \mu \rangle$, is, in fact, established due to the different populations of the electron energy levels, as a consequence of the fact that the magnetic field splits the S manifold of a particle with spin S according to its M_S values (Figure 2). The magnetic susceptibility per molecule, χ , is defined as

$$\chi = \frac{V_M \chi_V}{N_A} = \frac{V_M \mu_0 M}{N_A B_0} = \frac{\mu_0 \langle \mu \rangle}{B_0}$$

where V_M is the molar volume and N_A is the Avogadro constant.

The electron magnetic moment is related to the electron spin according to the following equation:

$$\boldsymbol{\mu} = -\mu_B g_e \mathbf{S}$$

where g_e is the electron g factor and μ_B is the electron Bohr magneton. The expectation value of $\boldsymbol{\mu}$ along the direction of the applied magnetic field z , is thus given by $-\mu_B g_e \langle S_z \rangle$. Analogously, the average induced magnetic moment per particle is

$$\langle \mu \rangle = -\mu_B g_e \langle S_z \rangle$$

where $\langle S_z \rangle$, the expectation value of S_z , in the high-temperature approximation and in the limiting case where there is no contribution from the orbital magnetic moment, is given by

$$\langle S_z \rangle = -\frac{g_e \mu_B B_0}{3kT} S(S+1)$$

where k is the Boltzmann constant and T is the absolute temperature. Therefore, the Curie law is obtained:

$$\chi = \mu_B^2 g_e^2 \frac{\mu_0}{3kT} S(S+1)$$

If the orbital magnetic moment is considered, the magnetic susceptibility becomes anisotropic, and must be represented as a tensor. As a consequence, the average induced magnetic moment depends on the orientation of the $\boldsymbol{\chi}$ -tensor with respect to the direction of the applied magnetic field:

$$\langle \mu \rangle = \frac{\boldsymbol{\chi} \cdot \mathbf{B}_0}{\mu_0}$$

The energy of a magnetically anisotropic molecule, with average magnetic moment per particle $\langle \mu \rangle$, in a magnetic field is given by

$$E^{\text{aniso}} = - \int_0^{\langle \mu \rangle} \mathbf{B}_0 \cdot d\langle \mu \rangle = - \frac{\mathbf{B}_0 \cdot \boldsymbol{\chi} \cdot \mathbf{B}_0}{2\mu_0}$$

The fact that the energy is orientation dependent has an influence on the probability that the molecule orients along different directions.

Figure 2 A magnetization arises due to the different population of the electron energy levels corresponding to $M_S = 1/2$ and $M_S = -1/2$.

The Dipole–Dipole Interaction

The point dipole–point dipole interaction between two particles possessing a magnetic moment is described by the Hamiltonian

$$H = -\frac{\mu_0}{4\pi} \left[\frac{3(\boldsymbol{\mu}_1 \cdot \mathbf{r})(\boldsymbol{\mu}_2 \cdot \mathbf{r})}{r^5} - \frac{\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2}{r^3} \right]$$

where μ_1 and μ_2 are the interacting magnetic moments and $\mathbf{r}$ is the vector connecting the two point dipoles (Figure 3). The magnetic moment of the proton is related to its spin I by the relationship $\mu_I = \hbar \gamma_I I$ where γ_I is the proton magnetogyric ratio and $\hbar = h/2\pi$ is the Planck constant. Therefore, if the dominant interaction is between a proton and the average induced electron magnetic moment, the dipolar Hamiltonian can be written as

$$H = -\frac{\hbar \gamma_I}{4\pi} \left[\frac{3(\mathbf{I} \cdot \mathbf{r})(\mathbf{r} \cdot \boldsymbol{\chi} \cdot \mathbf{B}_0)}{r^5} - \frac{\mathbf{I} \cdot \boldsymbol{\chi} \cdot \mathbf{B}_0}{r^3} \right] = \hbar \gamma_I \mathbf{I} \cdot \boldsymbol{\sigma} \cdot \mathbf{B}_0$$

where $\boldsymbol{\sigma}$ is called dipolar shielding tensor. In case a reference system is chosen with axes coinciding with the main directions of the $\boldsymbol{\chi}$ -tensor and origin on the metal ion, the dipolar shielding tensor is

$$\boldsymbol{\sigma} = -\frac{1}{4\pi r^5} \begin{pmatrix} (3x^2 - r^2)\chi_{xx} & 3xy\chi_{xy} & 3xz\chi_{xz} \\ 3xy\chi_{xy} & (3y^2 - r^2)\chi_{yy} & 3yz\chi_{yz} \\ 3xz\chi_{xz} & 3yz\chi_{yz} & (3z^2 - r^2)\chi_{zz} \end{pmatrix}$$

where χ_{xx} , χ_{yy} , and χ_{zz} are the principal components of the magnetic susceptibility tensor and x , y , and z are the coordinates of the nucleus in that reference system.

Pseudocontact Shift Restraints

The rotational average of the dipole–dipole interaction between the nucleus magnetic moment and the average induced electron magnetic moment causes a shift of the NMR signals, called PCS. It is calculated by taking the average of the values of the dipolar interaction energy along three principal directions, divided by the Zeeman energy $\hbar \gamma_I B_0$, and thus it is given by

$$\delta^{\text{PCS}} = -\frac{1}{3} \text{Tr}(\boldsymbol{\sigma})$$

Therefore, in the case where the reference frame coincides with the main directions of the $\boldsymbol{\chi}$ -tensor, with the metal ion in the origin,

$$\delta^{\text{PCS}} = \frac{1}{12\pi r^3} \frac{(3x^2 - r^2)\chi_{xx} + (3y^2 - r^2)\chi_{yy} + (3z^2 - r^2)\chi_{zz}}{r^2}$$

The latter equation can be written in spherical coordinates by using the ϑ and ϕ angles to specify the position of the nucleus in this reference frame,

Figure 3 The dipole–dipole interaction between two magnetic moments. The nuclear magnetic moment is along $\mathbf{B}_0$, whereas the electron magnetic moment can be along a different direction due to the anisotropy of the magnetic susceptibility tensor.

$$\delta^{\text{PCS}} = \frac{1}{12\pi r^3} \left[\Delta\chi_{\text{ax}} (3\cos^2\vartheta - 1) + \frac{3}{2} \Delta\chi_{\text{rh}} \sin^2\vartheta \cos 2\phi \right]$$

where $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$ are the axial and rhombic anisotropy parameters of the magnetic susceptibility tensor of the metal,

$$\Delta\chi_{\text{ax}} = \chi_{zz} - \frac{(\chi_{xx} + \chi_{yy})}{2}, \Delta\chi_{\text{rh}} = \chi_{xx} - \chi_{yy}$$

It should be noted that the PCS depends only on the anisotropy of χ and not on its magnitude. If the magnetic susceptibility is isotropic, the rotational average of the dipolar energy is zero, and no PCS occurs.

In conclusion, PCS restraints depend on the coordinates of the protein atom, on the values of the magnetic susceptibility anisotropies, and on the three Euler angles defining the principal frame of the magnetic susceptibility tensor. Figure 4 shows the form of the surface where a nucleus can stay, for a given positive (dark gray) or negative (light gray) value of the PCS and for a given magnetic susceptibility tensor, in the limiting cases of no ($\Delta\chi_{\text{rh}}=0$) and maximal ($\Delta\chi_{\text{rh}}=2\Delta\chi_{\text{ax}}/3$) rhombicity.

Relaxation Enhancement Restraints

The recovery to equilibrium of a nuclear spin system is characterized by two time constants, the longitudinal and the transverse relaxation times, indicated by T_1 and T_2 , respectively, or by their inverse R_1 and R_2 . The longitudinal relaxation time, also called spin–lattice relaxation time, is the time constant for the evolution of the component of the nuclear magnetization along the magnetic field direction toward its equilibrium value. The more numerous and efficient the mechanisms allowing the nuclear spin to jump from one nuclear energy level to another, the shorter the longitudinal relaxation time.

The transverse, or spin–spin, relaxation time is related to the lifetime of the magnetization component in the plane perpendicular to the magnetic field direction, which is zero at equilibrium. The mechanisms causing transverse relaxation comprise those causing longitudinal relaxation, but they are more numerous/efficient, and therefore $R_2 \geq R_1$.

The dipolar interaction energy between the electron spin magnetic moment and the proton magnetic moment can fluctuate in time due to changes in the metal–nucleus distance, for example, detachment of a coordinated molecule bearing the nucleus of interest, reorientation of the complex with respect to the external magnetic field, or changes in the M_z or M_{xy} components of the electron spin magnetic moment (electron relaxation). All these three processes represent mechanisms leading to nuclear relaxation, and thus causing the so-called paramagnetic enhancement of the longitudinal and transverse relaxation rates, R_{1M} and R_{2M} , respectively.

The resulting equation for R_{1M} is proportional to the average of the square of the dipolar interaction energy and to the appropriate spectral density functions:

$$R_{1M} = \frac{2}{15} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_I^2 g_e^2 \mu_B^2 S(S+1)}{r^6} \left[\frac{\tau_c}{1 + (\omega_I - \omega_S)^2 \tau_c^2} + \frac{3\tau_c}{1 + \omega_I^2 \tau_c^2} + \frac{6\tau_c}{1 + (\omega_I + \omega_S)^2 \tau_c^2} \right]$$

where $\omega_I = \gamma_I B_0$ is the proton Larmor frequency, ω_S is the electron Larmor frequency ($\omega_S = 658.2\omega_I$), and τ_c is the correlation time related to the mechanisms responsible for relaxation

$$(\tau_c^{\text{dip}})^{-1} = \tau_s^{-1} + \tau_r^{-1} + \tau_M^{-1}$$

Figure 4 Surface constraint for a nucleus with a positive (dark gray) or negative (light gray) PCS value in the case of (a) axial paramagnetic susceptibility tensor ($\Delta\chi_{\text{rh}}=0$) or (b) maximal rhombicity ($\Delta\chi_{\text{rh}}=2\Delta\chi_{\text{ax}}/3$) of the paramagnetic susceptibility tensor. The metal is located at the origin.

given by the shortest among the electron relaxation time τ_s , the reorientational time τ_r , and the exchange time τ_M . In metalloproteins, τ_c is generally equal to τ_s .

Analogously, the equation for nuclear transverse relaxation rate enhancement is

$$R_{2M} = \frac{1}{15} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_I^2 g_e^2 \mu_B^2 S(S+1)}{r^6} \left[4\tau_c + \frac{\tau_c}{1 + (\omega_I - \omega_S)^2 \tau_c^2} + \frac{3\tau_c}{1 + \omega_I^2 \tau_c^2} + \frac{6\tau_c}{1 + (\omega_I + \omega_S)^2 \tau_c^2} + \frac{6\tau_c}{1 + \omega_S^2 \tau_c^2} \right]$$

In the case of lanthanides and actinides, the term $g_I J(J+1)$, should replace $g_e S(S+1)$.

The former equations, calculated for systems without zero-field splitting and hyperfine coupling with the metal nucleus, are called Solomon equations. Such equations can be used to provide restraints for solution structure determination as they contain a dependence on the distance between the resonating nucleus and the unpaired electron(s) at the sixth power, thus being very effective for locating the metal ion in the protein frame and for determining nuclear-metal distances for protons close to the paramagnetic center.

The modulation of the dipole-dipole interaction of the nuclear spin with the average induced electron magnetic moment $\langle \mu \rangle$ provides a further relaxation contribution. This relaxation mechanism is usually called magnetic susceptibility relaxation or Curie spin relaxation. Such interaction, of course, cannot be modulated by the electron relaxation, since $\langle S_z \rangle$ is already an average over the electron spin states, and therefore the relevant correlation time is determined by τ_r (if τ_M is longer). The contributions to R_{1M} and R_{2M} provided by this mechanism (in the approximation of isotropic magnetic susceptibility) are

$$R_{1M} = \frac{2}{5} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\omega_I^2 g_e^4 \mu_B^4 S^2(S+1)^2}{(3kT)^2 r^6} \frac{3\tau_r}{1 + \omega_I^2 \tau_r^2}$$

$$R_{2M} = \frac{1}{5} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\omega_I^2 g_e^4 \mu_B^4 S^2(S+1)^2}{(3kT)^2 r^6} \left(4\tau_r + \frac{3\tau_r}{1 + \omega_I^2 \tau_r^2} \right)$$

In the case of lanthanides and actinides, the term $g_I^4 \mu_B^4 (J(J+1))^2$, or more properly the experimental μ_{eff}^4 value, when available, should replace $g_e^4 \mu_B^4 S(S+1)^2$.

The effect of Curie relaxation on R_{2M} , and thus on line widths, is very important in paramagnetic metalloproteins, especially at high magnetic fields, due to the large value of the reorientation time τ_r , compared to the normally shorter electron relaxation time, which appears in the Solomon equation. The effect on R_{1M} , which does not contain nondispersive terms, is instead usually negligible.

Cross-Correlation between Curie and Dipole-Dipole Relaxation Restraints

Another kind of restraint is the cross-correlation arising between the dipole-dipole interaction between two nuclei (for instance, N and H in a protein amide bond) and the dipolar interaction between the magnetic moment of one of the two nuclei and the average induced electron magnetic moment, both the interactions being modulated by the reorientation time. Such cross-correlation contributes to nuclear relaxation.

As for the cross-correlation present in diamagnetic systems between the dipole-dipole interaction and the chemical-shielding anisotropy, the cross-correlation between Curie and dipolar relaxation causes a difference in the line width of the two doublet components of, for example, the amide H (or the amide N). This difference in line width for the amide H, in the approximation of isotropic magnetic susceptibility, is given by

$$\Delta\nu_{1/2}^{CCR} = \frac{2}{15\pi} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{B_0 \gamma_H^2 \gamma_N \mu_B^2 g_e^2 S(S+1)}{r^3 r_{HN}^3 kT} \frac{3 \cos^2 \theta_{MHN} - 1}{2} \left(4\tau_r + \frac{3\tau_r}{1 + \omega_I^2 \tau_r^2} \right)$$

where the angle θ_{MHN} is that between the proton-nitrogen direction and the proton-metal ion direction and r is the proton-metal ion distance.

CCR restraints thus structurally depend on the inverse of the metal-proton distance at the third power and on the metal-proton-nitrogen angle. Their magnitude increases with the magnetic field and with the metal magnetic susceptibility, rather than with its anisotropy. Coupling between CH or CC pairs can also give rise to cross-correlation with Curie relaxation.

Self-Orientation Residual Dipolar Coupling Restraints

The dipole-dipole interaction between the magnetic moments of two unlike nuclei is given by

$$H = -\frac{\mu_0}{4\pi} \frac{\hbar^2 \gamma_A \gamma_B}{r_{AB}^3} I_z^A I_z^B (3 \cos^2 \gamma - 1)$$

where r_{AB} is the distance between the two nuclei A and B and γ is the angle between the interspin vector r and the external magnetic field, along which both the nuclear magnetic moments are quantized. The isotropic rotational average value of the dipolar coupling is zero. However, in case the different orientations are not all equally populated, different weights must be considered for the different directions, and therefore an RDC arises

$$\Delta\nu^{\text{rdc}} = \frac{\Delta E}{h} = -\frac{\mu_0 \hbar \gamma_A \gamma_B}{4\pi^2 r_{AB}^3} \left\langle \frac{3 \cos^2 \gamma - 1}{2} \right\rangle$$

This can be written as a function of an orientation tensor S :

$$\Delta\nu^{\text{rdc}} = -\frac{\mu_0 \hbar \gamma_A \gamma_B}{8\pi^2 r_{AB}^3} [S_{zz}(3 \cos^2 \Theta - 1) + (S_{xx} - S_{yy}) \sin^2 \Theta \cos 2\Phi]$$

where Θ is the angle between the AB vector and the z -axis of the orientation tensor, and Φ is the angle which describes the position of the projection of the AB vector on the xy -plane of the S -tensor, relative to the x -axis.

As noted already, the presence of an anisotropic metal magnetic susceptibility induces PCS. It can also contribute to partial orientation of the molecule in high magnetic fields.

The degree of alignment of a molecule relative to a magnetic field can be described by the principal components of the orientation tensor S , defined as

$$S_{ii} = \frac{\int \frac{3 \cos^2 \alpha - 1}{2} \exp\left[-\frac{E^{\text{aniso}}(\alpha, \beta)}{kT}\right] d \cos \alpha d\beta}{\int \exp\left[-\frac{E^{\text{aniso}}(\alpha, \beta)}{kT}\right] d \cos \alpha d\beta}$$

where α and β are the spherical angles describing the direction of B_0 in the molecular frame and $E^{\text{aniso}}(\alpha, \beta)$ is the anisotropic energy of the molecule in a field B_0 . Therefore, one obtains

$$S_{ii} = \frac{3}{2} \frac{B_0^2}{15\mu_0 kT} (\chi_{ii} - \bar{\chi})$$

The RDC due to paramagnetism can thus be expressed as a function of $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$,

$$\Delta\nu_{\text{rdc}}^{\text{para}} = -\frac{1}{4\pi} \frac{B_0^2}{15kT} \frac{\gamma_A \gamma_B \hbar}{2\pi r_{AB}^3} \left[\Delta\chi_{\text{ax}}(3 \cos^2 \Theta - 1) + \frac{3}{2} \Delta\chi_{\text{rh}} \sin^2 \Theta \cos 2\Phi \right]$$

where the angles Θ and Φ are defined in the principal frame of the paramagnetic susceptibility tensor. $\Delta\nu_{\text{rdc}}^{\text{para}}$ represents the difference in the measured 1J values between the paramagnetic system and a diamagnetic analog.

The functional form for PCS and RDC is the same. It is, however, important to note that the angles in the equation for RDC define the orientation of the coupled nuclei independently of their position with respect to the metal ion. Figure 5 shows the surface restraint determined by a given value of the RDC and a given magnetic susceptibility tensor with no and maximal rhombicity.

Contact Shift (and Hyperfine Shift) Restraints

CSs are due to the presence of unpaired electron spin density onto the resonating nucleus, which occurs through direct spin delocalization and/or spin polarization. CSs contain structural information because they are somehow related to chemical bonds, although only in a few cases this information can be translated into structural constraints.

Figure 5 Surface constraint for a nucleus with a positive (dark gray) or negative (light gray) RDC value in the case of (a) axial magnetic susceptibility tensor or (b) maximal rhombicity of the magnetic susceptibility tensor. The coupled nucleus is located on the origin.

In the case of $\text{Fe}_4\text{S}_4^{2+}$ clusters (Figure 6(a)), it has been found that the CS of the βCH_2 protons of coordinated cysteines depends on the FeSCH dihedral angle θ as

$$\delta^c = a \sin^2 \theta + b \cos \theta + c$$

where $a \cong 10.3$, $b \cong -2.2$, and $c \cong 3.9$ ppm. The dominant dependence on $\sin^2 \theta$ is ascribed to the fact that the spin density is in a p-orbital of the S-atom orthogonal to the Fe–S bond (Figure 6(b)). The relative values of the constant c with respect to a give an idea of the importance of the processes of electron delocalization through the σ -bond of Fe–S with respect to the π -bond of Fe–S. In these clusters, the observed hyperfine shifts are essentially CSs in origin.

The hyperfine shifts (given by the sum of contact and pseudocontact contributions) of heme methyl protons are given by the following heuristic equation in low-spin Fe(III) heme proteins containing a histidine and a cyanide as axial ligands, at 298 K,

$$\begin{aligned} \delta_i &= a \sin^2(\gamma_i - \alpha) + b \cos^2(\gamma_i + \alpha) + c \\ a &\cong 18.4, \quad b \cong -0.8, \quad c \cong 6.1 \end{aligned}$$

where γ_i is the angle between the metal–pyrrole II axis and the metal–*i*th-methyl direction, and α is the angle between the metal–pyrrole II axis and the direction of the histidine ring plane (Figure 7). In fact, the unpaired electron occupies one metal 3d-orbital that has the correct symmetry to form π -bonds with the axial ligand, and thus the contact contribution will be zero when the methyl protons lie in the nodal plane, and maximal when the methyl protons lie along the direction of the axial π -interaction, and thus $\delta_i^c \propto \sin^2(\gamma_i - \alpha)$. On the other hand, since the *z*-axis of the magnetic susceptibility tensor is always approximately perpendicular to the heme plane, the PCS is proportional to a function of the type $\delta^{\text{PCS}} \propto k \cos 2\phi - 1$, with the χ_x -axis rotated clockwise from the metal–pyrrole direction by an angle which is the same in magnitude, but opposite in direction, to the angle α . Therefore, $\phi = \gamma_i + \alpha$, and the equation given above is obtained.

Finally, the hyperfine shifts of methyl protons are given by the following heuristic equation in low-spin Fe(III) heme proteins containing two histidines as axial ligands:

Figure 6 (a) Cybane-type Fe_4S_4 cluster. (b) Dihedral angle θ between the Fe–S–C plane and the S–C–H plane in the case of the spin density being in a p-orbital of the S-atom orthogonal to the Fe–S bond.

Figure 7 The γ angles for the four methyl groups (indicated with a dot) are defined as the angles between the metal–methyl *i*th vector and the X-axis, taken along the metal–pyrrole II direction. The angle α defines the direction of the histidine ring plane.

$$\delta_i = \cos \beta [a \sin^2(\gamma_i - \alpha) + b \cos^2(\gamma_i + \alpha) + c] + d \sin \beta$$

$$a \cong 38.8, \quad b \cong -10.5, \quad c \cong -1.1, \quad d \cong 9.4$$

where α is the angle between the bisector of the angle β and the metal–pyrrole II axis, and β is the acute angle between the two histidine planes.

Similar considerations can be made for Fe(II) heme proteins with a single histidine in an axial position, when the electron configuration is high spin and the shifts of the methyl protons are determined by a mixture of σ - and π -delocalization mechanisms.

Collecting the Paramagnetism-Based Restraints

The NMR parameters that can be obtained by performing NMR experiments are the chemical shift, the longitudinal relaxation rate, and the transverse relaxation rate. For a given nucleus, the chemical shift is defined as the resonating frequency of the nucleus with respect to a reference signal (in Hz). The chemical shifts result from the sum of two contributions: the diamagnetic shift, arising from the shielding of the observed nucleus from the external magnetic field due to electrons around, and the paramagnetic shift or hyperfine shift, which consist of the pseudocontact and the contact contributions:

$$\delta^{\text{exp}} = \delta^{\text{dia}} + \delta^{\text{c}} + \delta^{\text{pcs}}$$

As seen earlier, the contact contribution is present only for nuclei close to the paramagnetic center, since it can arise only if electron spin density can be delocalized on the investigated nuclei. Therefore, only the pseudocontact term can affect the hyperfine shift of amino acids that are not directly bonded to the metal center or H-bonded to the donor atoms.

In order to calculate δ^{pcs} , it is necessary to evaluate δ^{dia} . This can be done, to a good approximation, by performing the measurements on the analog diamagnetic protein, obtained by removing the paramagnetic metal ion, by substituting the metal ion with a diamagnetic metal with the same charge, or by reducing the paramagnetic metal to a diamagnetic state.

PCSs have been measured, among others, in many low-spin iron(III) heme-containing proteins (Figure 8 shows those measured in cytochrome b_5) and in lanthanide-substituted calcium-binding proteins (e.g., calmodulin, parvalbumin, and calbindin). As noted previously, their magnitude depends on the magnetic susceptibility anisotropy of the metal. Estimates of the latter are reported in Table 1 for some metal ions. Figure 9 shows the observed PCS in the protein calbindin D_{9k} after substitution of Ce(III), Yb(III), or Dy(III) in the C-terminal calcium-binding site. Metal ions characterized by a small magnetic anisotropy (e.g., Ce(III)) permit one to obtain values only for nuclei at short distances, whereas metal ions characterized by a large magnetic anisotropy (e.g., Dy(III)), although they do not provide information for nuclei close to the metal ion, due to the excessive line-broadening caused by Curie relaxation, permit the observation of values for nuclei that are much farther away from the metal.

Once the PCSs have been used to determine the magnetic susceptibility tensor and the structure is known, the contact contribution to the hyperfine shifts for atoms in amino acids close to the metal ion can be obtained. In fact, the pseudocontact contribution for such atoms can be calculated and subtracted from the hyperfine shift.

Coupled nuclei experience 1J splittings of the observed nucleus signals. Such splittings can be measured in HSQC spectra or in J -modulated experiments, and are given by the sum of the diamagnetic 1J contribution, due to the scalar coupling and diamagnetic RDC, and the paramagnetic contribution. The values for $\Delta\nu_{\text{rdc}}^{\text{para}}$ can be obtained after subtraction of the 1J measured at the same field and temperature on the analog diamagnetic protein, obtained by removing the paramagnetic metal ion, by substituting the metal

Figure 8 Observed PCS for the heme protein cytochrome b_5 . The size of the balls is proportional to the magnitude of the negative (light gray) or positive (dark gray) PCS.

Table 1 Magnetic susceptibility and pseudo-contact shifts for some metal ion

	$\chi_{av}(10^{-32} \text{ m}^3)$	$\Delta\chi_{ax}(\%)$	δ^{PCS} for $r = 10 \text{ \AA}$ and $\theta = 0^\circ$ (ppm)

Yb(III)	15	45	3.6

**Figure 9** Observed PCS for the N and HN nuclei of the protein calbindin D_{9k} after substitution of (a) Ce(III), (b) Yb(III), or (c) Dy(III) in the C-terminal metal binding site. The size of the balls is proportional to the magnitude of the negative (light gray) or positive (dark gray) PCS.**Figure 10** Observed self-orientation RDC for the HN atoms of the protein calbindin D_{9k} after substitution of Ce(III) in the C-terminal metal binding site.

ion with a diamagnetic metal with the same charge, or by reducing the paramagnetic metal to a diamagnetic state. Paramagnetic RDCs have been measured for many metalloproteins. Those related to the protein Ce(III)-calbindin D_{9k} are shown in **Figure 10**.

Relaxation rates are also measured as the sum of the diamagnetic and the paramagnetic contributions. Again, the diamagnetic contribution can be evaluated by performing measurements on the diamagnetic analog of the protein, by removing the paramagnetic metal ion or by substituting it with a diamagnetic one. Another way to estimate the diamagnetic contribution consists in taking an average among all the experimental relaxation rates that are below a given threshold value in the paramagnetic metalloprotein. In fact, R_{1M} is proportional to r^{-6} , and thus it becomes negligible for nuclei far from the paramagnetic center, whereas it is dominant for nuclei close to the paramagnetic center.

Transverse relaxation rates are related to signal line widths. The difference in the line width (in Hz) measured at half-height of, for example, the two components in the proton dimension of the HN doublet in the HSQC spectra of ¹⁵N enriched paramagnetic metalloproteins is given by $\Delta\nu_{1/2}^{\text{CT}}$, and it can be used as an additional restraint for protein solution structure determination. **Figure 11(a)** reports the observed values for amide proton cross-correlations between Curie and dipolar relaxation in the Ce(III)-substituted protein calbindin D_{9k}, and **Figure 11(b)** reports the CCR values observed in metaquomoglobin.

Figure 11 Observed CCR for the HN atoms (a) of the protein calbindin D_{9k} after substitution of Ce(III) in the C-terminal metal binding site, (b) of met-myoglobin, a heme protein containing high-spin Fe(III).

Solution Structure Determination Programs

Calculations of the solution structure of metalloproteins by employing paramagnetism-based restraints are normally performed using a modified version of the program CYANA, called PARAMAGNETIC CYANA, or the Xplor-NIH package. Both programs use molecular dynamics for energy minimization combined with a simulated annealing algorithm to calculate a family of structures starting from randomly generated conformers. Any metal ion and the relative magnetic susceptibility tensor axes are represented using pseudo-atoms as shown in **Figure 12**.

The paramagnetism-based restraints are introduced by calculating a pseudopotential E_l for each class of new restraints

$$E_l = \sum_i w_i [\max(|X_{i,\text{obs}} - X_{i,\text{calc}}| - \text{tol}_i, 0)]^2$$

to be added to the global target function, which is the quantity to be minimized. The index i runs over all experimental data of the considered class of restraints; tol indicates the tolerance, and w_i the weighting factor for that restraint. $X_{i,\text{obs}}$ represents the experimental data and $X_{i,\text{calc}}$ the calculated values in the present protein configuration according to the equations provided above.

PARAMAGNETIC CYANA and PARArestraints for Xplor-NIH use the PCS and RDC restraints by keeping fixed the values of the magnetic susceptibility anisotropies during the annealing process. These parameters ($\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$), which can be initially estimated from theoretical predictions, can be obtained by fitting the observed data on the protein structure (using, for instance, the program FANTEN). Therefore, both their values and the protein structure are actually obtained by a few cycles of structure calculations and fit on the protein structure, until convergence is reached.

Recovering Information on Structure Heterogeneity

Several proteins can experience some conformational variability, so that their structure cannot be represented by a single conformation. The paramagnetism-based restraints are very effective in providing evidences of this conformational heterogeneity.

Figure 12 A pseudoresidue is defined containing pseudo-atoms needed to represent in the protein frame the position of the metal ion and the directions of the principal axes of the magnetic susceptibility anisotropy tensor.

The paramagnetic relaxation enhancements are averaged over conformations that interconvert at rates larger than the nuclear relaxation rate, and larger than the differences in nuclear chemical shifts among the different conformations. Due to the r^{-6} distance dependence, the contributions to R_{1M} and R_{2M} from conformations where r is small are much larger than from conformations where r is large. Experimental paramagnetic relaxation enhancements can thus monitor the occurrence of lowly populated protein conformations with nuclei much closer to the paramagnetic metal than in the highly populated states.

In the presence of conformational variability, PCSs and RDCs are averaged over the values corresponding to the different conformations sampled by the system (if the interconversion rate is larger than the differences in nuclear chemical shifts among the different conformations). The measurement of paramagnetic RDCs can provide a quick way to estimate the presence of conformational rearrangement between the protein domain containing a paramagnetic ion and any other domain. In fact, in rigid systems, the RDC-determined magnetic susceptibility anisotropy $\Delta\chi_{(ax)}$ must be the same for all domains, whereas, in the case of interdomain mobility, the RDCs of the domain without the metal provide a reduced magnetic susceptibility anisotropy, as a result of the conformational averaging.

Recovering the structural ensemble from average data is, in mathematical terms, an ill-posed inverse problem, which admits an infinite number of solutions. In fact, we can determine possible ensembles of conformations providing averaged PCS, RDC, and/or R_{1M} and R_{2M} values in agreement with the experimental data. However, there is an infinite number of ensembles which may agree equally well with the experimental data.

Ensemble averaging approaches can be used to estimate the extent of the conformational heterogeneity and retrieve some conformations which may be representatives of the protein structure variability. This can be done by recovering the maximum entropy solution or by recovering ensembles composed of the smallest number of conformations providing agreement with the experimental data. To evaluate how much a given conformation can contribute at most to the experimental average, the Maximum Occurrence (MaxOcc) of conformations can be determined. The MaxOcc is defined as the largest weight that a conformation can have within any ensemble and be still in agreement with the experimental data. Using an analogous approach, the MaxOcc can also be calculated for ensembles of conformationally close structures.

Paramagnetic Tagging of Diamagnetic Proteins

The information content of paramagnetism-based restraints is so effective that diamagnetic proteins are sometimes conveniently tagged with paramagnetic metal complexes, so that PCS and/or RDC data can be measured. Lanthanide tags are mostly used because many of them have the largest magnetic susceptibility anisotropy, and thus are those providing the largest PCSs and RDCs; furthermore, the whole series of lanthanide ions (diamagnetic as well as paramagnetic) can be replaced in the same position, so that multiple datasets of paramagnetic data can be easily obtained.

A lanthanide binding tag can be genetically encoded and expressed as fusion tag together with the protein, or can be a synthetic tag that ligates specific residues. Tag rigidity is an important requisite, because the internal mobility of a tag causes a reduction in the amplitude of the RDCs (which implies a smaller signal-to-noise ratio) and provides averaged PCSs perturbed by this mobility. Rigidity can be achieved (1) by two-point attachment of the tag to nonmobile residues on the surface of the protein, through disulfide bridges, after cysteine replacement of the protein residues at the desired binding positions; (2) by anchoring to the target protein in a first position via a disulfide bridge and in a second position through the N-terminal fusion, (3) by a single covalent bond and additional coordination of the paramagnetic ion by an amino acid of the protein, or (4) by a bulk metal ion binding cage attached through a single covalent bond.

Conclusion

It has been shown that paramagnetism-based restraints can provide relevant information for solution structure determination of paramagnetic metalloproteins, both around the metal ion and in the whole protein. CS can, in fact, identify the metal ligands and can provide dihedral angle restraints on the metal ligands. PCSs contain information on the coordinates of the metal ion and on the position of the protein atoms in the frame of the magnetic susceptibility tensor. Nuclear relaxation rates provide metal–nucleus distances. Cross-correlations contain information on distances and angles among the metal ion and coupled nuclei. Selforientation RDCs provide information on the orientations of internuclear vectors in the magnetic susceptibility frame. All these restraints are vital for obtaining information around the metal ion, where it is usually missing, and can actually be precious to increase the accuracy of the protein structure. Furthermore, it is demonstrated that they provide enough information to be an alternative to classical diamagnetic restraints for protein solution structure determination.

Introduction

Photosynthesis is the transformation of light energy into fuel that drives essential life processes in a variety of organisms. The physics of photosynthesis is photophysics: the collection and handling of sunlight and its conversion to a more stable form of energy. The subsequent utilization of this light energy involves a series of chemical reactions, which taken together comprise the global biological function of photosynthesis. In this article, the focus is on the fundamental steps of photosynthesis. The article begins by looking at the nanoscale machines involved, and then follows the path of an absorbed photon of sunlight as it journeys through the photosystem until eventually being converted into chemical potential.

It is worth bearing in mind that the total time of this phase of photosynthesis is not more than 100 ps, yet it is packed with numerous small steps, each of which has now been resolved in exquisite detail. Since the 1980s, photosynthetic complexes have been crystallized and analyzed to the atomic level. At the same time, lasers have been replacing the Sun in laboratory studies with increasingly better time resolution, such that one can now initiate and follow the flow of energy and charge in real time. This combination of detailed structural and dynamic information has opened a new window on photosynthesis, revealing the importance of these fundamental physical processes on the overall biological function.

Photosynthetic Machinery

Photosynthesis occurs in plants, algae, and some bacteria. The photosynthetic apparatus of all these organisms contains two key components responsible for the primary photophysics: light-harvesting (LH) complexes and reaction centers (RCs). Both are sophisticated pigment–protein structures located within cell membranes, and while they are necessarily coupled, each has a unique task. The light-harvesting complexes capture photons and transfer the solar energy both within and between complexes until it reaches the reaction centers, where this energy is then used to shuttle electrons across the photosynthetic membrane.

The essential components of photosynthesis can be viewed as nanoscale machines arranged in a complex web (rather than a linear assembly line operation) for optimal performance. **Fig. 1** shows the photosynthetic apparatus responsible for collection and conversion of solar energy for the case of purple nonsulfur bacteria. These primitive organisms serve as prototype species for studies of the physics of photosynthesis. Unlike plant systems, the various components of the photosynthetic apparatus in these bacteria can be easily isolated and purified. In some species, these components have been crystallized, allowing atomic-level structural information to be extracted. Also, the genetic makeup of these systems is known, allowing site-specific mutagenesis in which individual amino acids in the protein matrix can be altered. Such mutants are invaluable in studies aimed at detailed structure–function relations.

Fig. 1 shows schematically a top-down look at the photosynthetic membrane of purple bacteria, based on real structural data. The ring-like structures are light-harvesting (LH) complexes. These complexes contain cylindrical aggregates of alpha-helical proteins (not shown) that span the lipid bilayer membrane and noncovalently bind the pigment molecules in circular or elliptical arrays. Nestled within one of these rings is another pigment–protein complex, the so-called reaction center (RC). This complex contains two branches with near mirror symmetry, also spanning the photosynthetic membrane. The overall supramolecular aggregate of peripheral light-harvesting complexes LH2 and core complexes containing the RC and surrounding LH1 complex is called the photosynthetic unit (PSU), though the ratio of LH2 to LH1-RC varies according to growth conditions such as temperature and light intensity.

[☆]*Change History:* May 2016. F.T. Mahi added Abstract, Keywords, Figures and expanded text with additional review materials. Updated the list of references.

Fig. 1 Schematic representation of the photosynthetic machinery of purple nonsulfur bacteria, based on crystallographic data. For clarity, the protein and carotenoid molecules are omitted. The peripheral light-harvesting complex LH2 contains two circular aggregates of bacteriochlorophyll molecules, labeled B800 and B850 according to their characteristic absorption maxima at 800 and 850 nm. Likewise, the larger core light-harvesting complex LH1 contains a broken ellipse of aggregated bacteriochlorophylls, the B880 ring. Nestled within the LH1 complex is the photosynthetic reaction center (RC). The supramolecular aggregate of LH2, LH1, and RC complexes is called the photosynthetic unit.

In the intricate network of molecules arranged within the protein matrix, the function is determined by the location. While a chlorophyll molecule in the reaction center plays an essential role in photochemistry, a chlorophyll molecule located in an antenna complex functions in a completely different manner. These functions are described in the following sections.

Harvesting Light

The first step of photosynthesis is the collection of sunlight. How is light captured by living things? Illuminated molecules may either reflect or absorb incident light. Molecules that are especially capable of absorbing light in the visible region of the spectrum and give color to living things are called pigments. The pigments of photosynthesis are primarily chlorophylls, of which there are many different varieties. These molecules efficiently absorb light in the red and blue regions of the solar spectrum, while reflecting away most of the green (hence the predominance of this color in Nature). In addition, a variety of other less-abundant pigments enhance the light-absorbing capabilities of photosynthetic organisms by capturing other regions of the visible spectrum. Carotenoids, for example, have strong absorption in the blue-green region, but reflect away the yellow to red wavelengths. These pigments are largely responsible for the autumn “colorama,” showcasing the presence of the carotenoids that becomes gloriously apparent as the chlorophyll in the leaves of the trees begins to break down.

When a molecule absorbs a photon of visible light, one of its electrons is promoted to a higher energy state. The molecule is then said to be in an electronic excited state. The wavelengths of light that are capable of creating excited states for a given molecule are given by an absorption spectrum. In **Fig. 2**, the absorption spectra of chlorophyll and carotenoid molecules are shown, in comparison with the solar irradiance spectrum on Earth. The entire visible range of light (400–700 nm) as well as much of the near-infrared (up to 1000 nm) is used to drive photosynthesis in different organisms.

Understanding the excited states in photosynthesis is a key area of biophysics research, as it is from these states that all physical processes such as energy transfer and trapping as well as chemical reactions may occur. The nature of the excited state depends not only on the characteristic properties of the individual molecule, but also on its specific location within the photosynthetic complex. Interactions between neighboring pigments and, to some extent, the surrounding protein can shift the excited-state energies and thereby affect dynamics. For example, in photosynthetic purple bacteria, the primary pigment is bacteriochlorophyll. The main absorption of this pigment when isolated in solution is at ~ 780 nm. In the photosynthetic unit, however, the absorption band shifts according to its location (and corresponding function): in the peripheral light-harvesting complex (LH2), there are two distinct binding sites for bacteriochlorophyll, giving rise to absorption bands at 800 and 850 nm, respectively. These binding sites are correspondingly labeled B800 and B850; see **Fig. 1**. In the B800 ring, the individual pigments are well separated (by ~ 20 Å), and the spectral properties are determined mainly by weak interactions with the protein environment. In the B850 ring, however, the pigments are tightly packed in a “waterwheel” arrangement; the further red-shifted absorption of the molecules here is due to the much stronger excitonic coupling between adjacent pigments. The ring structure also enhances absorption and acts as an energy storage unit. In the LH1 core light-harvesting complex, which directly couples to the reaction center, the bacteriochlorophyll absorb

The spectra of the pigments are in absorption units (scale not shown).

at 880 nm, and have an arrangement similar to the B850 ring. This tuning of absorption properties with location is crucial to the overall function of photosynthesis, creating an energy hierarchy that efficiently funnels light energy into the reaction center.

Grieco *et al.* (2015) has investigated and presented a new model for the excitation energy distribution in plant thylakoids. Also assigned a role to the fraction of Light Harvesting Complex II denoted as “extra-LHCII.” Extra LHCII ensures energetic connectivity between Photo System II (PSII) and Photo System I (PSI). The whole LHCII constitutes an antenna “lake” in which PSII and PSI are embedded. LHCII phosphorylation is a regulator, but not a necessity, for the connectivity. Fig. 3 illustrates the process.

Antenna Action: Energy Transfer

While the reaction center is the hotspot for photosynthetic energy conversion, by itself it can only capture a few photons per second (given its absorption cross section, the solar flux, and its overlap with the solar irradiance spectrum). Yet, the turnover time of the reaction center function is of the order of 10 ms, that is, it is capable of a much higher throughput. Hence, an antenna system evolved to catch extra photons and feed them to the reaction center.

Antenna networks are highly regulated to maximize the efficiency of energy collection while at the same time avoiding photodamage that can occur when too much light is absorbed. These functions occur by rapid and directional energy transfer reactions. Following absorption of solar light, the pigment molecules are in electronically excited states. In principle, this excitation energy may then be used directly to drive a chemical reaction. However, in photosynthesis, the energy is first transferred between many molecules, over quite large distances, before it arrives at the site of action.

The antenna system increases the amount of sunlight that can be absorbed compared to a single pigment, thereby increasing the number of photons available for photochemistry. A photosynthetic antenna is analogous to a satellite dish, collecting energy from a large area and concentrating it at a small receiver site (the reaction center), thereby greatly increasing the signal strength. Antenna networks contain an additional 100–10,000 pigments per reaction center. Molecules located in the antenna do not perform any chemistry, but simply transfer the collected energy between each other in a well-defined and efficient manner. For optimal functioning, energy collected by the antenna pigments must reach the reaction center within ~100 ps; hence, the transfer between individual pigments should be of the order of 1 ps or less. This transfer process is purely physical and is governed by the energetic interactions between molecules.

Advances in ultrafast laser spectroscopy have allowed detailed measurements of these energy transfer dynamics in real time. In the laboratory, a femtosecond laser replaces the sun and initiates the process of interest. As the absorption of the antenna pigments is determined by their location, the laser may be tuned to be resonant with a given molecule, thereby isolating a specific energy transfer step. For example, in the LH2 complex of purple bacteria, the B800 to B850 energy transfer can be targeted by tuning an excitation pulse to 800 nm, and then probing the arrival of energy by monitoring the buildup of the transient absorbance signal at 850 nm with a second delayed femtosecond pulse. By varying the timing of the probe pulse, the dynamics of the process may be followed at discrete time steps, which, when combined, yield a kinetics trace.

All photosynthetic systems have an inherent energy gradient that dictates the flow of energy among the pigments. In purple bacteria, this is given by B800→B850→B880→RC (note that the valuable contributions of carotenoids, which perform accessory

Fig. 3 Schematic representation of the distribution of photosystems and their antennae in the thylakoid membrane (A) and the possibilities of excitation energy flow in the PSII and LHCII rich grana core ((B)–(C)) and in the more exposed domains with high amount of PSI also ((D)–(F)). (A) PSII–LHCII complexes and the PSI complexes are enriched in the grana core and peripheral domains of thylakoid disks, respectively. Both PSII and PSI are present at peripheral areas of the grana disks. A considerable amount of LHCII trimers is interposed between the photosystems and all LHCII trimer populations are partially phosphorylated (for clarity, the phosphorylation of PSII is not shown). (B) Light is absorbed by an LHCII trimer, thus forming an excitation energy packet (exciton) that is transferred to an open PSII center. (C) Exciton moves from LHCII to a closed PSII and subsequently reaches an open PSII through LHCII connectivity. Toward the peripheral areas of the grana disks ((D)–(F)), the probability that exciton can move through LHCII connectivity to PSI increases. In the absence of LHCII phosphorylation, the probability that exciton can enter to PSI is low. The LHCII phosphorylation, however, modulates the molecular interaction in the antenna lake to enhance energy trapping by PSI (D). (G) PSII and PSI can be in contact, allowing direct energy spillover from PSII to PSI.

Fig. 4 Energy transfer times between the various pigments in the photosynthetic units of purple bacteria.

light harvesting in addition to other important functions, are ignored). The associated time constants for these transfer steps are shown in Fig. 4. The lifetime of an isolated antenna complex, decoupled from the reaction center, is of the order of 1 ns. During this time, the excitation energy moves freely among the lowest-energy pigments of the antenna network, until eventually dissipated by nonradiative relaxation processes. In the full photosynthetic unit, where antennas are connected to reaction centers, the excitation is trapped within 30–50 ps. Hence under physiological conditions, nearly all the energy is utilized for photochemistry.

Excitation transfer in biological systems has usually been described as an incoherent hopping process following the theory of Förster. It is hard to overestimate the physical insight obtained by this approach. At the same time, a number of experimental observations for photosynthetic pigment–proteins do not fit into this picture and call for a more general description of the problem. The incoherent Förster description of electronic energy transfer assumes that the interaction between the involved molecules is very weak. In the opposite limit of strong interaction between the molecules, a molecular exciton description is appropriate. In this limit, the excited states of the individual molecules combine to exciton states common for all the interacting molecules (the aggregate), the excitation is coherently delocalized over a number of pigment molecules and the absorption spectrum exhibits a prominent exciton band structure. Time evolution in the exciton picture occurs via phonon-induced relaxation between exciton levels. These two descriptions, incoherent hopping and exciton relaxation, are the two qualitatively different limiting cases of the general process of excitation dynamics. What description should be chosen for a particular observation depends on the system properties and the experimental conditions. It may happen that the real situation is somewhere in between these two limiting cases, in which case the analysis is particularly challenging.

The important factor in deciding which process(es) occur is the ratio of the coupling between electronic transitions (V) and the disorder (Δ). The disorder may be either static (spectral inhomogeneity) or dynamic (electron–phonon interaction). If V/Δ is much less than unity, then the interactions are considered very weak and energy transfer occurs in the incoherent Förster hopping regime. In the opposite case, if $V/\Delta \gg 1$, the interaction is very strong and the exciton picture is used. In both cases, the transfer rate can be calculated using the first-order perturbation theory leading to the Fermi Golden rule. In the hopping description, the electronic coupling (V) acts as a perturbation; in the exciton picture, an electron–phonon coupling (dynamic disorder) is the perturbation.

In the weak coupling incoherent limit, the rate of energy transfer (energy hopping) from a donor to an acceptor molecule is determined by three different molecular properties: the electronic coupling between donor and acceptor (V), the overlap of donor fluorescence and acceptor absorption spectra (J), and the relative orientation of the molecules (κ), and given by

$$K_{\text{ET}} \sim V^2 J \kappa^2$$

A few things should be noted. The electronic coupling (V) has two contributions, one short-range electron-exchange interaction (which decays exponentially with the intermolecular distance R) and one long-range Coulombic interaction (which scales as R^{-6}). These two cases are described in Fig. 5. The interaction accounted for in the Förster mechanism and implicated by the transition dipoles is the generally dominating dipole–dipole contribution to the Coulombic interaction; higher multipole terms are also generally present, but of much less importance for molecules with strong transition dipole moments (eg, strongly allowed optical transitions). The electron exchange term in the interaction may become important at very short distances, when there is overlap of the donor and acceptor molecular orbitals. This is the so-called Dexter mechanism, and in particular for molecules with forbidden optical transitions, it may become important. Energy transfer in photosynthetic antenna complexes between the lowest forbidden excited state of carotenoid molecules and the lowest excited state of chlorophyll molecules has been discussed in terms of the Dexter mechanism.

In the exciton picture, the excitation energy is delocalized over the interacting pigment molecules. However, the extent of delocalization is determined by the V/Δ ratio, and in a real system, exciton delocalization is generally smaller than the physical size of the molecular aggregate. The localization process may also have a dynamic part due to the dynamic contribution to the disorder Δ , and the exciton thereby changes its size in time. The relevant aspects of the energetics and dynamics in the exciton limit are the exciton level structure, the dynamics of exciton relaxation among the set of exciton levels, the extent and dynamics of delocalization of the exciton, and the motion of the whole exciton over the aggregate of interacting molecules. The energies of the exciton states are obtained from the Hamiltonian of the interacting molecules and the dynamics may be obtained from the density matrix of the system.

Fig. 5 Interactions governing excitation energy transfer. The Coulombic interaction promotes simultaneous deactivation of the donor and excitation of the acceptor. The electron exchange interaction involves transfer of excitation energy via direct exchange of electrons between donor and acceptor molecules.

Fig. 6 Model of one of the possible supramolecular structures formed by LHCII under the presence of exogenous Vio. Endogenous neoxanthin displayed in red color and exogenous Vio displayed in yellow color.

Janik *et al.* (2016) studied the effect of violaxanthin and zeaxanthin, two main carotenoids of the xanthophyll cycle, on molecular organization of LHCII, the principal photosynthetic antenna complex of plants, in a model system based on lipid–protein membranes, by means of analysis of 77K chlorophyll a fluorescence and “native” electrophoresis. Violaxanthin was found to promote trimeric organization of LHCII, contrary to zeaxanthin which was found to destabilize trimeric structures. Moreover, violaxanthin was found to induce decomposition of oligomeric LHCII structures formed in the lipid phase and characterized by the fluorescence emission band at 715 nm. Both pigments promoted formation of two-component supramolecular structures of LHCII and xanthophylls. The violaxanthin-stabilized structures were composed mostly of LHCII trimers, while the zeaxanthin-stabilized supramolecular structures of LHCII showed more complex organization which depended periodically on the xanthophyll content. The effect of the xanthophyll cycle pigments on molecular organization of LHCII was analyzed based on the results of molecular modeling and discussed in terms of a physiological meaning of this mechanism. Supramolecular structures of LHCII stabilized by violaxanthin, prevent uncontrolled oligomerization of LHCII, potentially leading to excitation quenching, therefore can be considered as structures protecting the photosynthetic apparatus against energy losses at low light intensities. Fig. 6 illustrates the process.

Energy Conversion and Storage

Electron transfer reactions are Nature’s solution to the problem of converting the short-lived energy of electronically excited molecules into a more stable form of energy, which can, in addition, be transformed into various energy-rich substances with practically unlimited storage potential. Nature has devised highly efficient systems that optimize electron transfer processes while at the same time avoiding back-reactions and quenching processes.

When the excitation energy reaches the photosynthetic reaction center, it launches a sequence of electron transfer reactions that create a charge-separated state in which positive and negative charges are separated over the lipid bilayer membrane. Energy stored in this manner can then be used to pump protons across the membrane. The resulting proton motive force drives the synthesis of energy-rich compounds such as adenosine triphosphate (ATP). ATP is thermodynamically stable for a sufficiently long time to serve as the “fuel” for many subsequent biochemical processes. Once stored in the form of ATP, the energy can be used in the cell at any arbitrary instant for transport, synthesis, or other chemical reactions that require input energy.

Again, of all the photosynthetic organisms, the reaction center of anoxygenic purple bacteria is best understood. Though in contrast to the wide variety in the configurations of antenna complexes, the reaction centers of bacteria and plants share a rather common structural and functional motif. The reaction center consists of a number of protein subunits that form a scaffold (not shown) to hold the photochemically active molecules. While a number of these molecules are identical or similar to the (bacterio) chlorophyll pigments found in the antenna, here the molecules are called cofactors to distinguish their different function. The structure of the reaction center from *Rhodobacter sphaeroides* is shown in Fig. 7. The cofactors are bacteriochlorophylls (P and B in

Fig. 7 X-ray structure of the active molecules in the reaction center from the photosynthetic purple bacteria *Rhodospirillum rubrum*, showing the pathway and time constants of electron transport via the active branch A.

Fig. 7), bacteriopheophytins (H), quinones (Q), and an iron atom (located between the quinones; not shown). The cofactors are arranged into two nearly symmetric branches (A and B), joined at the top by the so-called “special pair” of bacteriochlorophyll molecules that are located so close together as to form a super molecule or dimer.

When the excitation energy collected by the antenna network finally arrives at the reaction center, it initiates a cascade of electron transfer reactions. These reactions have been visualized by a variety of spectroscopic techniques, in particular ultrafast transient absorption spectroscopy, often combined with genetic manipulations of the native structure to better elucidate structure–function relations. Upon light irradiation, the excited dimer (P) transfers an electron to the bacteriochlorophyll (B_A) and the bacteriopheophytin (H_A) on the A side of the branch within a few ps. The resulting radical pair ($P^+H_A^-$) decays in about 200 ps moving the electron onward to the quinones.

The most striking feature of the reaction center activity is the unidirectional transport down branch A (the active branch), despite the apparent twofold symmetry of the structure. The electron is 200 times more likely to follow branch A than branch B. Although considerable experimental and theoretical efforts have tackled this discrepancy, it remains as one of the most intriguing puzzles in the primary processes of photosynthesis.

The high quantum yield of primary charge separation (as much as 0.95 in some systems) comes with a price: a lower energetic yield. The final radical pair state of the bacterial RC contains 0.55 eV, which is only 40% of the excited state energy of the primary electron donor (or around a third of the average photon energy absorbed by the antenna). Perhaps the energetic efficiency of the RC could be improved upon in synthetic RC-like structures, though model systems (consisting of electron donor and acceptor molecules connected by covalent links) have shown quantum efficiencies of 30% or less. Most likely, the rigidity of the protein surrounding the donor and acceptor pigments is essential to achieve such high quantum efficiency.

From Natural to Artificial Photosynthesis

An understanding of how Nature works will allow one to use the basic principles for other purposes. The most obvious application of artificial photosynthesis is the conversion of sunlight to useful forms of energy, such as electricity by photovoltaic devices or fuel by photochemical reactors. Modern solar cells are already being built on principles gleaned from natural photosynthesis. Sensitized semiconductor materials are environmentally friendly and becoming cost-effective alternatives to silicon. Solar cells based on this material utilize sensitizer molecules that act as antenna pigments to collect sunlight in a wide spectral region and funnel the solar energy into the semiconductor by way of an electron transfer process. Ongoing research will lead to the development of new, more efficient solar light-harvesting technologies that not only mimic Nature, but perhaps also surpass it.

House *et al.* (2015) investigated that the artificial photosynthesis converts and stores solar energy through solar fuels. Dyesensitized photoelectrosynthesis (DSPEC) cells are used for artificial photosynthesis. In a DSPEC, molecular assemblies absorb light and carry out chemical catalysis. Higher efficiencies and stabilities are required for useful devices. Fig. 8 shows some examples of energy storage technologies and their relative stages of development.

Fig. 8 Examples of energy storage technologies and their relative stages of development. Technologies based on artificial photosynthesis are highlighted in red.

The Need for Biomedical Materials

Improving healthcare and technology are increasing life expectancy but as one ages the body parts cannot maintain their function. Tissues such as bone and cartilage are needed to support the aging body even though the cells that produce them become less active with age. The heart, kidneys, and liver have to operate for much longer than ever before. This entry discusses how biomedical materials and biophysics techniques are being used in the development of regenerative medicine procedures. The aim of regenerative medicine is to regenerate diseased and damaged tissue to its original state and function.

Bone Defects

Bone is a natural composite of collagen (polymer) and bone mineral (ceramic). Collagen is a triple helix of protein chains, a complex structure that has high tensile and flexural strength and provides a framework for the bone. Bone mineral is a crystalline calcium phosphate ceramic (hydroxyapatite (HA), $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) that provides stiffness and the high compressive strength of the bone. The two most important types of bone are cortical and cancellous bone. Cortical bone is a dense structure with high mechanical strength and is also known as compact bone. Cancellous or trabecular bone is an internal porous supporting structure present in the ends of long bones such as the femur or within the confines of the cortical bone in short bones. The trabecular bone is a network of struts (trabeculae) enclosing large voids (macropores) with 55–70% interconnected porosity.

The mechanism for natural bone generation/regeneration in the body is the secretion of extracellular matrix by osteogenic cells (osteoblasts), which have developed (differentiated) from stem cells. The extracellular matrix is collagen type I, which mineralizes to form bone mineral, creating a composite of orientated collagen fibrils and apatite. The bone is remodeled in response to its local loading environment by the body. Osteoclasts are cells that resorb old bone and bone that is not required (i.e., not under any load), while osteoblasts lay down new bone.

Osteoporosis is a disease where bone resorption occurs faster than new bone is produced, causing the trabeculae to become thinner which leads to a reduction in total bone density and strength. The disease eventually leads to fracture of bones especially in the hip, wrist, knee, and spine. At present, when osteoporotic fracture occurs in knees and hips, joint replacement is often required. Millions of orthopedic prostheses made of bioinert materials have been implanted, an example of which is the Charnley total hip replacement, which is heralded as one of the most successful surgical inventions.

Long-term monitoring of 20000 Charnley joints has revealed that it has a survivability of 76% after 25 years implantation, that is, 24% of hip operations required revision surgery. Improved metal alloys, special polymers, and medical-grade ceramics are the basis for this success, which has enhanced the quality of life for millions of patients. Reasons for failure tend to be aseptic loosening of the femoral stem, where bone resorption occurred due to a mismatch in the Young's modulus of the bone and the metal stem. Many modifications and variations of the Charnley joint have been developed over the years, including coating the metal stem with

a synthetic HA layer that can bond to the bone mineral in the bone; however, survivability studies are so far only medium term and have shown similar results to that of the Chamley prosthesis.

A New Direction

All present day orthopedic implants lack three of the most critical characteristics of living tissues: (1) the ability to self-repair; (2) the ability to maintain a blood supply; and (3) the ability to modify their structure and properties in response to environmental factors such as mechanical load. All implants have a limited lifespan and as life expectancy is continually increasing, it is proposed that a shift in emphasis from “replacement” of tissues to “regeneration” of tissues is required to satisfy this growing need for very long-term orthopedic repair.

One way to restore diseased or damaged tissue to its original state and function would be the successful engineering of the replacement tissue in the laboratory. In a typical tissue engineering application, cells would be harvested from the patient (i.e., osteogenic cells in the case of bone) and seeded on a synthetic scaffold that acts as a guide and stimulus for tissue growth in three dimensions creating a tissue engineering construct or living biocomposite. The biocomposite would then be implanted back into the patient. Over time, the synthetic scaffold should be resorbed into the body as nontoxic degradation products at the same rate that the cells produce their own extracellular matrix.

In this article, the development of scaffold technology is discussed, focusing primarily on porous glass scaffolds that bond to bone and the growth of bone and cartilage in the laboratory on such scaffolds. The biophysics techniques that are now being used to monitor cell behavior as the cells grow are also discussed.

Biomedical Materials

Any material that is implanted into the body should be biocompatible, that is, not cytotoxic (not toxic to cells). There are three classes of noncytotoxic materials; bioinert, bioactive, and bioresorbable. No material is completely inert on implantation, but the only response to the implantation of bioinert materials is encapsulation of the implant by the fibrous tissue. Examples of bioinert materials are medical-grade alumina, stainless steels, and high-density polyethylene that are used in the total hip replacements.

Resorbable materials are those that dissolve on contact with body fluids and the dissolution products can be secreted via the kidneys. The most common biomedical resorbable materials are polymers that degrade by chain scission such as polyglycolic (PGA) and polylactic acids (PLLA) and their co-polymers, which are commonly used as sutures.

Bioactive Materials

Bioactive materials stimulate a biological response from the body such as bonding to tissue. Bone is a natural composite of bone mineral (HA) and collagen and other proteins. Therefore, synthetic HA (with Ca/P=1.667) and other calcium phosphate ceramics, including coral, have gained much attention as a bone mineral substitute.

There are two classes of bioactive materials; class B bioactive materials bond to hard tissue (bone) and stimulate bone growth along the surface of the bioactive material (osteoconduction). Examples of class B bioactive materials are synthetic HA and tricalcium phosphate ceramics. Synthetic HA has been used in several clinical applications such as a bone defect filler and is used to coat the stainless steel or titanium alloy shaft of the total hip prosthesis so that it bonds to the thigh bone (femur). Tricalcium phosphate (β -TCP, with Ca/P=1.5) is an osteoconductive material that is also resorbable in the body. β -TCP is usually used in conjunction with synthetic HA to improve the resorbability of HA in applications such as the filling of bone defects left by cysts, sinus floor augmentation, and bone cements.

Class A bioactive materials not only bond to bone and are osteoconductive but they are also osteoproducer, that is, they stimulate the growth of new bone on the material away from the bone/implant interface and can bond to soft tissue such as gingival (gum) and cartilage. Examples of class A bioactive materials are bioactive glasses. A certain composition of melt-derived bioactive glass (46.1% SiO₂, 24.4% Na₂O, 26.9% CaO, and 2.6% P₂O₅, in mol), called Bioglass[®] is used in the clinic as a treatment for periodontal disease (Perioglas[®]) and as a bone-filling material (Novabone[®]). Bioglass[®] implants have also been used to replace damaged middle ear bones, restoring hearing to thousands of patients.

The mechanism of bone bonding to bioactive materials is thought to be due to the formation of an HA layer on the surface of the materials after immersion in body fluid. This layer is similar to the apatite layer in bone and therefore a strong bond can form. The layer forms quickest on class A bioactive materials. The mechanism of formation of the HA layer on bioactive glasses is shown in Figure 1. Stage 1 involves release of cations. Stage 2 is the break up of the silica-based glass network. These two stages are dissolution processes; therefore, these glasses are not only bioactive but are also resorbable in the body. β -TCP ceramics are also resorbable.

Figure 2 shows suggested mechanisms for osteoproduction, where new bone grows on bioactive glasses away from the glass--host bone interface. The sequence follows on from the events in Figure 1 but concentrates on the effects of the glass on the cells within the bone and bone marrow, however it does not fully explain osteoproduction. Recent findings by Professor Dame Julia Polak's team at the Tissue Engineering and Regenerative Medicine Centre at Imperial College, London, have shown that the dissolution products of bioactive glasses up-regulate seven families of genes that regulate osteogenesis and the production of growth factors.

Figure 1 Mechanism of formation of the HCA layer on the surface of bioactive glasses in solution.

Figure 2 Suggested mechanism of cellular interactions between cells and bioactive glasses after implantation, after the formation of the HCA layer.

Composites

To overcome the low toughness of HA, a polyethylene-HA composite was developed by Professor William Bonfield and colleagues at the University of London. It is clinically available under the name HAPEX™ and has been used as middle ear implants and orbital floor replacements. The polymer provides toughness strength and the HA increases the compressive strength and provides bioactivity so that implants are not encapsulated by scar tissues. The composite is class B bioactive and is easily shaped with a scalpel by the surgeon and so is now routinely used to replace the bones of the middle ear.

Scaffolds for Bone Repair

The Criteria for an Ideal Scaffold

To be able to regenerate the trabecular bone, a construct is required that will mimic the structure and mechanical properties of the trabecular bone and stimulate new bone growth in the shape dictated by the scaffold. Therefore, the scaffold should have a structure that acts as a template for tissue growth in three dimensions. The template must be an interconnected macroporous network containing pores with diameters in excess of 100 μm to promote cell migration, tissue ingrowth and vascularization, and nutrient delivery to the center of the regenerating tissue on implantation. The scaffold material should be able to bond to the host bone without the formation of scar tissue, that is, it should be made from an osteoconductive material. If the bone is to be restored to its original state, the scaffold should be resorbable so that eventually there is no trace of the scaffold's presence. The degradation rate of the scaffold must be controllable so that it can be tailored to match the rate of bone growth. The dissolution products would ideally influence the genes in the bone generating stem cells to stimulate efficient cell differentiation and proliferation. Importantly, the

mechanical properties of the scaffold should match that of the host bone and not decrease too rapidly during degradation so that bone regeneration occurs at load-bearing sites.

If the scaffold is to be mass produced so that surgeons can use it in the clinic, it must be made from a processing technique that can produce irregular shapes to match that of the defect in the bone of the patient. It must have the potential to be producible to the required ISO (International Standards Organization) or FDA (Food and Drug Administration) standards and be easily sterilized.

The need for implant materials to pass the FDA standards may be necessary for the safety of patients, but it places a large financial obstacle in the path of new scaffold developments. Many researchers use materials that have already been passed by the FDA so that they are sure their scaffold will be safe for use in the clinic. They are unwilling to risk using materials that have not undergone FDA testing because of the time and financial commitment required for fulfilling the extensive tests.

Polymer Scaffolds

Resorbable polymeric scaffolds have been developed with porous structures similar to the trabecular bone. There are three reasons why much effort has been put into using polymers as scaffolds. First, polymers are easy to process in the shape of a 3D scaffold with a pore morphology suitable for a tissue engineering application with techniques such as phase separation, gas foaming, freeze drying, combined solvent leaching and extrusion, and computer-controlled rapid prototyping techniques. Polymer fibers can be woven together using textile processing techniques.

Second, polymers can have high tensile properties and high toughness. The mechanical properties of polymers can be controlled very easily by changing the molecular weight (chain length) of the polymer. Third, bioresorbable polymers have been successfully used as dissolving sutures for many years. Therefore, these degradable polymers, such as the esters PGA and PLLA, have passed FDA regulations and can be implanted into the body.

There are however some problems with using biodegradable polymers as scaffolds for bone regeneration. First, while a degradable scaffold is desired, sutures dissolve within 2 weeks of implantation, which is too rapid for bone regeneration applications.

Second, although resorbable polymers can be made with high tensile strength and toughness and their mechanical properties can be matched with collagen, their Young's modulus is much lower than that of bone, therefore these polymers cannot be used in load-bearing sites where they undergo compressive forces.

A third problem is that the mechanical strength of polymers decreases rapidly as they degrade. High tensile strength polymers have long chains (high molecular weight), which entangle with each other. As a tensile force is applied to the entangled chains, the chains begin to unravel until they become straight. The maximum tensile strength of polymers is reached when the chains are fully extended. Therefore, for a polymer to be tough, it must have a molecular weight over the entanglement value. The mechanism for degradation of biodegradable polymers is chain scission. The polymers undergo hydrolysis and the chains are cut in two. The average molecular weight of the polymer is therefore approximately halved with every chain scission event. The mechanical properties of the polymer are proportionate to the square root of the molecular weight and therefore decrease very rapidly as the polymer degrades. Biodegradable polymers have also been found to produce an inflammatory response due to the acidic by-products of the degradation.

Bioactive Ceramic Scaffolds

Ceramics are crystalline materials and tend to have high compressive strength and Young's modulus but low toughness, that is, they are brittle materials. Alumina and synthetic HA are ceramics that are most commonly used in biomedical applications. Alumina is a bioinert ceramic that is very hard and resistant to wear. It is therefore commonly used as a replacement to the ball of the femur in total hip replacement. Bioactive ceramics that have been used as bone regeneration materials are synthetic HA and β -TCP. Synthetic HA has been used most regularly because of its similarity to bone mineral; it has a similar structure and Young's modulus. β -TCP is similar to bone mineral in that they are both calcium phosphate ceramics, however β -TCP is resorbable.

In a porous form, HA and β -TCP ceramics can be colonized by bone tissue. A problem with introducing pores into a ceramic is that the compressive strength of the material decreases dramatically. The strength of the scaffold depends on the thickness and strength of the struts or pore walls. Generally, for the brittle compression of a foam

$$\sigma_{cr} \propto \rho_r^{3/2} \quad [1]$$

where σ_{cr} is the critical strength of the pore walls and ρ_r is the relative density, expressed as

$$\rho_r = \rho_b / \rho_s \quad [2]$$

where ρ_b is the bulk density of the scaffold and ρ_s is the skeletal (true) density of the material.

The simplest way to generate porous scaffolds from ceramics such as HA, is to sinter particles, preferably spheres of equal size. The scaffolds can then be pressed using cold isostatic pressing. As the sintering temperature increases, the pore diameter decreases, and mechanical properties increase as the packing of the spheres increases. Mechanical properties can be increased

further by hot isostatic pressing (HIPing). High mechanical strengths can be achieved but the pore diameter is not high enough. Porosity can be increased by adding fillers such as sucrose, gelatine, and polymethyl methacrylate (PMMA) microbeads to the powder slurry, which burnout on sintering. However, this technique decreases the compressive strength to below that of the trabecular bone.

The majority of methods that are used to produce polymer foams cannot be applied to ceramic systems. However, a popular method for producing highly porous ceramics is to produce a polyurethane foam template that can be immersed in ceramic slurries under vacuum to allow the slurry to penetrate into the pores of the foam. The organic components are burnt out and the ceramic foams sintered (1350°C) producing a scaffold with interconnected pore diameters of up to 300 µm.

The ceramic slurries can also be foamed to obtain pores in the range of 20 µm up to 1–2 mm. The incorporation of bubbles is achieved by injection of gases through the fluid medium, mechanical agitation, blowing agents, evaporation of compounds, or by evolution of gas by *in situ* chemical reaction. A surfactant is generally used to stabilize bubbles formed in the liquid phase by reducing the surface tension of the gas–liquid interface. Surfactants are macromolecules composed of two parts, one hydrophobic and one hydrophilic. Owing to this configuration, surfactants tend to adsorb onto gas–liquid interfaces with the hydrophobic part being expelled from the solvent and a hydrophilic part remaining in contact with the liquid. This behavior lowers the surface tension of the gas–liquid interfaces, making the foam films thermodynamically stable, which would otherwise collapse in the absence of the surfactant.

The gel-casting method has been the most successful method used to produce macroporous bioactive HA ceramics with interconnected pores of greater than 100 µm in diameter. Suspensions of HA particles and organic monomers are foamed by agitation with the addition of a surfactant under a nitrogen atmosphere. *In situ* polymerization (cross-linking) of the monomers, which is initiated by a catalyst, creates a 3D polymeric network (gel). The porous gels are sintered to provide mechanical strength and to burnout the organic solvents. HA foams have been made with compressive strengths in excess of 10 MPa, which is similar to that of trabecular bone. When the foams were implanted into the tibia of rabbits, bone partially filled the pores after 8 weeks and there was no inflammatory response. The compressive strength of the scaffolds that were colonized by bone trebled.

Hydrated silicon (SiOH₄) has been found to be a major contributor to the mineralization of bone and gene activation, which has lead to the substitution of silica (SiO₂) for calcia (CaO) into synthetic HA. *In vivo* results showed that bone ingrowth in silica-substituted HA granules was significantly greater than that into phase pure HA granules.

The disadvantages of an HA scaffold over a bioactive glass scaffold with similar morphology are that HA resorbs only very slowly, the dissolution products do not stimulate the genes in the osteogenic cells and HA is only osteoconductive as it generates bone at a slower rate than bioactive glasses. HA is still a bone replacement material rather than a regenerative material.

Bioactive Glass Scaffolds

Theoretically, gel-casting could be applied to melt-derived bioactive glass powders. However, bioactive glasses undergo surface reactions on contact with solutions to produce an HCA surface layer and it is desirable to have control over the reaction before a scaffold is ready for clinical use.

Sacrificial porogens and foaming agents have also been used to create melt-derived bioactive glass (Bioglass®) scaffolds. Large pores with diameters in the region of 200–300 µm were created but the total porosity was just 21% and there were large distances between pores, so this process failed to mimic the interconnectivity of the trabecular bone.

The most successful method for the production of bioactive glass scaffolds of similar structure to trabecular bone mineral is the foaming of sol–gel derived bioactive glasses. The sol–gel process involves polymer reactions of the glass precursors in a solution (sol). The sol is a solution of silica species that forms a gel by cross-linking together into a silica network. Sol–gel derived bioactive glasses tend to be more bioactive and resorb quicker than melt-derived glasses of similar compositions. The compositions of gel-glasses can also contain fewer components while maintaining bioactivity. This is due to them having a textural nano-sized porosity that is inherent to the sol–gel process, which provides a specific surface area of 150–600 m² g^{−1}, which is two orders of magnitude higher than melt-derived glasses. Along this surface there are many silanol groups that act as nucleation sites for HCA layer formation (Figure 1).

During the foaming process, air is entrapped in the sol under vigorous agitation as viscosity increases and the silica (–Si–O–Si–) network forms. A surfactant is added to stabilize the bubbles at short times. As the porous foam becomes a gel, the bubbles are permanently stabilized. The gel is then subjected to controlled thermal processes of aging (60°C) to strengthen it, drying (130°C), and thermal stabilization/sintering to remove organic species from the surface of the material (500–800°C). Bioactive glass foam scaffolds can contain macropores up to 600 µm in diameter, connected by pore windows with modal diameters in excess of 100 µm and compressive strengths up to 2.5 MPa. Figure 3 shows a scanning electron microscopy (SEM) micrograph of a pore network of a typical bioactive glass foam. *In vitro* cell studies using primary human osteoblasts have shown the foams stimulate formation and mineralization of bone nodules within 2 weeks of culture (Figure 4). Figure 4 shows osteoblasts that have attached to the concave surface of the pore. The cells have proliferated, coating the pore in an organic layer, and have released extracellular matrix, which has mineralized to form bone mineral. *In vivo* studies have shown that foam scaffolds implanted on rabbit crania stimulated new bone growth at a similar rate to that of the melt-derived bioactive glass powder available commercially.

Spectroscopy and Biophotonics

Vibrational spectroscopy is one of the most common techniques to study the surface reactions of bioactive materials. It is nondestructive, rapid, and can be used to analyze small areas of a sample surface. The two most commonly used vibrational spectroscopy techniques are Fourier transform infrared spectroscopy (FTIR) and Raman spectroscopy.

Fourier Transform Infrared Spectroscopy

FTIR spectra have been used to determine the rate of formation of the HCA layer on bioactive glasses and the technique is used as a quality assurance (QA) test for bioactivity. FTIR spectra of the glass surface area usually taken after a glass sample has been reacted in simulated body fluid (SBF) and dried. The crystalline HCA layer is characterized by the P–O bending vibration bands at 560 and 604 cm^{-1} (infrared wave number). Stretching and bending vibration bands for the amorphous silica network are also present in the spectra. The relative intensity of the bands can be used to monitor growth of the layer as a function of time. Figure 5 shows FTIR spectra of three forms of the sol–gel derived bioactive glasses of the 58S composition (60 mol.% SiO_2 , 36 mol.% CaO , 4 mol.% P_2O_5) that were soaked in SBF for 2 h. The spectra show that the HCA layer thickness was thicker for the powders and foams with respect to the monolith. Although FTIR can be used for the characterization of dried materials after soaking or after implantation and removal, *in situ* measurements are hindered by the strong adsorption of water in the infrared region.

Figure 5 FTIR spectra for 58S glass powder, foam, and monolith after 2 h immersion in SBF at 37°C and 175 rpm agitation.

Bio-Raman Spectroscopy and Biophotonics

Raman spectra are fingerprints of the chemical composition of the material. Raman spectra are obtained by collecting electromagnetic radiation that has been scattered by molecules (Raman effect). The spectral shifts depend on the vibrational frequencies of the molecules. The low Raman signal and low Raman scattering of water, and the combination of Raman spectroscopy with optical microscopy (water immersion objectives) has allowed noninvasive *in situ* monitoring of cells in cell culture. This technique is called micro-Raman spectroscopy. The optical objective provides high spatial resolution and is used to locate the cell or part of the cell, such as the cytoplasm or the nucleus, from which a spectrum will be collected. A laser is then fired at the identified area and the scattered photons are collected by a detector.

Low scattering efficiency of the cells makes the measurement of Raman shifts difficult. Raman signals can be enhanced using UV lasers; however, high-powered lasers can denature the cells and change cell phenotype. Decreasing the laser power decreases the Raman signal, but reduces the risk of changes to the cell. A laser wavelength of 785 nm has been found to produce optimal *in situ* spectra of living cells. A single spectrum obtained from the nucleus of a cell can contain information about the protein and DNA content of the cell. Figure 6 shows a Raman spectrum of a cultured lung cell containing vibrational bands corresponding to DNA (A, G, T, C adenine, guanine, thymine, cytosine), BK: backbone, RP: ribose-phosphate and the proteins phenylalanine (Phe) and tyrosine (Tyr). Raman spectroscopy using 785 nm lasers can be used to monitor the biochemical changes taking place in a cell. During cell death, for example, the degradation of proteins, DNA breakdown, and the formation of lipid vesicles can be detected in real time.

Cells cultured on bioactive materials can also be monitored by *in situ* Raman spectroscopy. A background spectrum for the unreacted material can be subtracted from the spectrum of a cell on the material. The resultant spectrum will then also contain vibrational bands corresponding to the formation of any calcium phosphate layer on the surface of the bioactive material as a function of time.

Raman spectroscopy may hold the key for the *in situ* monitoring of bone cells growing on scaffolds. When acquisition techniques and interpretation of the spectra are perfected, the micro-Raman spectrometers can be linked to bioreactors and the effect of flow rates, growth factors, and dissolution products on cell behavior can be monitored in real time.

Conclusion

Numerous materials have been developed to replace living tissues. They are bioinert (stainless steel, alumina), bioresorbable (polyglycolic acid), or bioactive (synthetic HA and bioactive glasses). New biocomposites have been made that combine bioinert and bioactive properties. The latest generation of materials are used in combination with cells. Many techniques have been employed to produce porous scaffolds. The scaffold that most closely matches the criteria for an ideal scaffold and that most closely mimics the structure of the trabecular bone is the bioactive glass foam. However, these scaffolds do not yet have the

Figure 6 Raman spectrum of a cultured living lung cell. (Courtesy of I Notingher.)

mechanical properties to be directly implanted into load-bearing sites. Ideally, a bioactive glass/polymer foam composite would be developed with improved toughness. The properties of a scaffold must be optimized with respect to the cell response to the scaffold. Biophotonics techniques such as Raman spectroscopy have the potential to be able to monitor cell activity and intracellular processes of living cells in real time noninvasively.

EDITOR-IN-CHIEF BIOGRAPHY

Tapash Chakraborty is a retired professor of physics from the University of Manitoba, Canada, where he was also the Canada Research Chair in Nanoscale Physics (2003–17). His research focus has been on many-body theories of various quantum materials, such as nuclear matter, helium liquids, and electron-hole liquids, that he studied under the tutelage of late Professor Manfred Ristig, at the University of Köln (1979–81). Just a year after the discovery of the fractional quantum Hall effect, he (working with his coworkers) demonstrated that electron–electron interactions could actually lead to quantum Hall states with nontrivial spin configurations, and that the low-lying excitations could be described as “spin-reversed quasiparticles.” This prediction motivated much experimental work from laboratories around the world, as a result of which the concept of spin-reversed quasi-particles was established.

Similarly, his work on the quantum Hall states in double layer systems has received much attention from the community. Furthermore, Dr. Chakraborty (working with Dr. P. Maksym and others) made pioneering contributions to the many-electron theory of quantum dots. Dr. Chakraborty has also contributed to the theory of electronic properties of various nanoscale systems, such as spin-orbit coupled quantum dots, quantum rings, and single- and double-layer graphene (primarily with Dr. V. Apalkov). He has authored many books and reviews: the book with Dr. Pietiläinen on the quantum Hall effect and the single-authored book on quantum dots have become standard references in their respective fields.

INTRODUCTION

Electrons in orbits contained by the quantum,
And atoms conjoined by the dipolar force,
Gravity balanced by pressure
And flap of a wing.
Here, I remember the angles and curves,
Calculus, I learned it all –
Each bird bit and moon fracture
Fixed by the symmetries,
Airborne and airless, aloft.

– Alan Lightman: *Song of Two Worlds*

Condensed matter physics (CMP) is the largest discipline in physics, involving a wide variety of interesting concepts and challenges. To quote [Leggett \(1992\)](#), CMP embraces topics “as diverse as traditional solid-state physics, neutron stars and the physics of biological matter.” He further added that, by a liberal definition “just about all of physics outside atomic, nuclear and particle physics and cosmology” fall in this vast enterprise¹. One of the primary goals of CMP is to explore the fundamental properties of matter—solids, liquids or gasses—comprising a large number of *interacting* constituent particles ([Laughlin and Pines, 2000](#)). The quantum-mechanical nature of these many-body systems makes condensed-matter highly nontrivial, sometimes counterintuitive and even astonishing. Superconductivity and the fractional quantum Hall effect (FQHE) naturally fall within that category. In fact, for the past four decades, the quantum Hall effects (QHEs) have been the epitome of elegant CMP ([von Klitzing et al., 2020](#)). Our fundamental system of units has been redefined following the discovery of the QHE when the “von Klitzing constant” $R_K = 25,812.8074593045 \, \Omega$ came into being ([von Klitzing, 2019](#); [Nawrocki, 2019](#)). Observation of the QHE in graphene² was crucial in determining the Dirac nature of charge carriers there (see for example, [Jiang et al., 2007](#)).

Another effect that outwardly resembles the QHE but is conceptually quite different is the FQHE, which is a quintessential manifestation of electron correlations governed by the Coulomb interaction ([Störmer, 1992](#); [Eisenstein and Stormer, 1990](#)). To explain this fascinating effect, [Laughlin \(1983\)](#) introduced his eponymous wave function that not only provided the foundation for understanding the effect but also triggered a new wave of ideas with impact far beyond the realm of CMP³. Who would have imagined that a large collection of interacting electrons confined on a plane in a perpendicular magnetic field would result in elementary excitations (quasiholes and quasiparticles) ([Chakraborty and Pietiläinen, 1988, 1995](#); [Halperin, 1983](#); [Clark and Maksym, 1989](#)) carrying fractional electron charge and obeying the exotic exchange statistics of anyons ([Halperin, 1984](#); [Arovas et al., 1984](#))? These quasiparticles and quasiholes of the Laughlin state still remain an enigma ([Laughlin, 1984](#); [Chakraborty, 1985](#); [Morf and Halperin, 1986](#)). Fractional statistics is a truly path-breaking concept in CMP that was introduced by [Leinaas and Myrheim \(1977\)](#), and has been recently confirmed experimentally ([Bartolomei et al., 2020](#); [Nakamura et al., 2020](#)).

Much of the history of CMP can be viewed as a series of paradigm shifts⁴. The field evolved rapidly through frequent ground-breaking discoveries that challenged existing paradigms and opened up new applications, and this evolution is expected to continue ([Leggett, 2018](#); [Cohen, 2008](#)). For example, our current understanding of

¹Interestingly, some similarities do exist between the mathematical frameworks that describe low-temperature CMP and early-universe cosmology. See [Kibble and Srivastava \(2013\)](#).

²An isolated single layer of graphite consisting of carbon atoms bonded together in a hexagonal structure. See, e.g., [Abergel et al. \(2010\)](#).

³For example, an important aspect of Laughlin's theory is its seamless concinnity of classical plasma physics and the planar electron gas that has inspired others to use a similar approach to quark-gluon plasma ([Lu, 2022](#)).

⁴A detailed exposition of the meaning and examples of “paradigm shifts” (Kuhn-type) can be found in [Leggett \(2018\)](#).

the FQHE required deep mathematical analysis and a wide range of experimental exploration, which revealed a treasure trove of unique phenomena that are yet to be fully understood or explained. Other studies of electron correlations in low spatial dimensions have ushered in many groundbreaking notions, such as Pfaffian states, Majorana fermions in condensed matter, Chern insulators, and topological quantum materials that promise a fault tolerant means to perform quantum computation. The presence of incompressible FQHE states in monolayer graphene (Apalkov and Chakraborty, 2006), bilayer graphene (Apalkov and Chakraborty, 2010, 2011), and double-layer graphene (Liu et al., 2019) has demonstrated the robustness of the effect, and provides invaluable insight into the nature of this effect.

The dynamics of an electron in a periodic potential subjected to a perpendicular magnetic field has been an intriguing problem for more than half a century (Obermair and Wannier, 1976; Osadchy and Avron, 2001)⁵. Within the nearest neighbor tight-binding description of the periodic potential the electron energy spectrum is described by the Harper equation (Harper, 1955). Numerical solution of this equation (Hofstadter, 1976) has revealed that the applied field splits the Bloch bands into subbands and gaps. As the field is varied, the splitting of band continues indefinitely, leading to bands within bands within bands. When plotted as a function of the magnetic flux per lattice cell, the energy spectrum depicts a *fractal* pattern (a self-similar pattern that repeats at every scale) and is known in the literature as Hofstadter's butterfly because of the resemblance of the pattern to butterflies⁶. Observation of the butterfly spectra in real systems is an arduous task. For example, in ordinary crystalline lattices, the required magnetic field to see the butterflies exceeds 1000 Tesla, which is far beyond the reach of present-day technology. Graphene seems to be the ideal system in the quest of those fractal butterflies (Weiss, 2013). It is interesting to note that a mathematical solution of the Harper equation, in contrast to the numerical solution mentioned above, remained a challenging problem (the so-called Ten Martini Problem) for mathematicians until it was solved (Avila and Jitomirskaya, 2006) in 2006.

Magnetism has been known to mankind since ancient times, and it remains a major topic in CMP. The road to understanding magnetism has been long and tortuous. At various times in history, magnets were claimed to have the healing power to cure a myriad of ailments that included epilepsy, arthritis, gout, and baldness. Magnets were the prime ingredients for the "elixir of life" by Paracelsus (1493–1541). Then there was the healing process of "animal magnetism" proposed by Franz Anton Mesmer (1734–1815) (mesmerism)⁷, which was famously mocked in Mozart's *Così fan tutte* (Stephoe, 1986). Our current understanding of magnetism is deeply rooted in quantum mechanics as Van Vleck explained (Van Vleck, 1978): "Quantum mechanics is the key to understand magnetism. When one enters the first room with this key there are unexpected rooms beyond, but it is always the master key that unlocks each door." For centuries, the magnetism of certain rocks and metallic iron was only used for the practical purposes of direction finding, particularly navigation with a compass. Motors, generators, and electrical distribution networks appeared only in the 19th century after the discovery of the deep connection between electricity and magnetism. Magnetic order is a collective phenomenon akin to superconductivity and superfluidity that involves a very large number of particles. The rich variety of magnetically ordered states in solids, not only ferromagnetism but also antiferromagnetism, ferrimagnetism, and a range of noncollinear structures, was confirmed only in the middle of the 20th century, with the availability of neutron beams in research reactors. A range of new magnetic materials are taking their place as active layers in thin film sensors and memory devices (Baltz et al., 2018). Besides information storage (Blundell, 2001), important technical applications include magnetic resonance imaging (MRI) and the use of magnetic nanoparticles in medicine.

Many outstanding discoveries in magnetism and magnetic materials have resulted in rapid advances in information storage technology. Over the last two decades spintronics has emerged as an important field of research both from the point of view of fundamental science and advanced technological applications (Yamaguchi et al., 2021; Pinarbasi and Kent, 2022). The giant magnetoresistance (GMR) effect, the spin Hall effect, and the spin galvanic effects are typical examples of developments in the field. Spintronics aims at understanding how the spin degree of freedom of the electrical carriers can be controlled in order to obtain devices with new functionalities and better performance. This endeavor often combines concepts from different aspects of condensed matter systems, giving the topic a fascinating interdisciplinary flavor. Spintronic phenomena are now being studied in an impressive range of different materials ranging from metals to half-metals to semiconductors, graphene and other two-dimensional systems such as transition metal dichalcogenides.

⁵For a recent review on butterflies in graphene, see for example Chakraborty and Apalkov (2015).

⁶However, as one of the authors of this Encyclopedia has (somewhat humorously) pointed out, this butterfly has Lebesgue measure zero, that is, it cannot fly!.

⁷A wonderful account of the use of magnetism in medicine since ancient times can be found in Mourino (1991).

The GMR effect and the related tunnel magnetoresistance effect (TMR) found their first commercial use in magnetic field sensors for hard-disk read-heads, before broadening their field of application to include magnetic sensors for the automobile industry, solid-state compasses, biosensors, and nonvolatile magnetic memory (Hartmann, 2000). The ability to manipulate the magnetic state of ferromagnetic structures led to initial developments in spintronics, where the spin direction was controlled by externally applied magnetic fields. However, the push for downscaling and faster timescales has prompted research advances in the past decade where the manipulation of magnetic configurations is achieved by local electric currents (the spin torque effect) (Brataas et al., 2012; Locatelli et al., 2014). In recent years, various novel concepts, such as chiral spintronics, skyrmionic spin textures, and magnetic domain walls in spintronics, have been actively pursued. The rate of progress in spintronics is truly astounding (Editorial, 2022).

In the past century, superconductivity has raised many theoretical challenges and triggered numerous technical developments. Discovered in mercury in 1911, this unique phenomenon occurs when the electrical resistance of many metals and alloys drops to zero when cooled below about 4 K, the temperature of liquid helium. More significantly, the material expels magnetic flux and becomes perfectly diamagnetic. Superconductivity has been adopted or evaluated for a wide range of technical applications (Rogalla and Kes, 2012). These include electric power generation, electric power transmission, high-speed maglev transportation, and ultra-strong magnetic field generation in high-resolution MRI and other nuclear magnetic resonance (NMR) systems. Interestingly, it took almost 50 years after the original discovery for the phenomena to be explained by the BCS theory (Tinkham, 2004) of reciprocal-space electron pairing, via the electron–phonon interaction. This electron–phonon mediated superconductivity became known as “conventional superconductivity” after the discovery of “high-temperature superconductivity” (Müller and Bednorz, 1987) at liquid nitrogen temperatures in tetragonal copper oxides in 1986. This threw open a new challenge to explain the properties of strongly correlated *anisotropic* electronic systems. Further new classes of superconductors that remain to be properly understood include the iron-based pnictides discovered in 2008 (Hosono et al., 2018). Recently, a two-dimensional superlattice made from a twisted bilayer of “magic angle” graphene was found to exhibit unconventional superconductivity (Cao et al., 2018), driven by electron–electron interactions.

The phenomenon of spontaneous symmetry breaking (SSB) is ubiquitous in physics, and plays a fundamental role in CMP, particle physics, and even in cosmology. A classic illustration of SSB being Heisenberg’s 1928 paper on ferromagnetism (Heisenberg, 1928). It is responsible for various collective modes, such as the famous Nambu-Goldstone (NG) and Higgs modes. Named by Baker and Glashow (Baker and Glashow, 1962), SSB corresponds to the case where the ground or lowest-energy state does not have the symmetry of the underlying dynamics. Instead, multiple degenerate ground states are available and the symmetry breaking is *spontaneous* because it is not clear, a priori, which one of those ground states will be chosen. In this well-trodden territory a simple analogy of this abstruse concept given by A. Salam is illuminating (CERN, 1977): “Imagine a banquet where guests sit at round tables. A bird’s eye view of the scene presents total symmetry, with serviettes alternating with people around each table. A person could equally well take a serviette from his right or from his left. The symmetry is spontaneously broken when one guest decides to pick up from his left and everyone else follows suit.” Over the years, development of the concept of SSB has taken a circuitous route (Gaudenzi, 2022): “from the land of particle physics to the physics of many bodies (solids and nuclei), from there to the province of superconductivity, and from the latter back to particle physics” SSB’s significance extends beyond the physics of the Higgs boson to the study of low-energy phenomena such as superconductivity, superfluidity, magnetism, and others. Historically, the particle physics community has been guided by this exploration in their quest to understand and discover particles like the Higgs boson. More to the point, when a continuous symmetry is spontaneously broken, a gapless mode, the NG mode, appears which governs the low-energy behavior of the system. As an example, in a solid, the acoustic phonon is the NG mode associated with translational symmetry breaking and determines the behavior of the specific heat at low temperature (the Debye T^3 law). Recently, signatures of Higgs and Goldstone modes have been proposed to exist in a perovskite oxide (Marthinsen et al., 2018), in other crystalline structures (Vallone, 2019), and also in various other quantum systems (Léonard et al., 2017). On a lighter note, it is the symmetry breaking that is claimed to have prevented the fabled donkey (Weintraub, 2012) in the parable by Jean Buridan (1300–50) from dying of starvation (Fubini, 1974).

Common to the theoretical descriptions of these phenomena across CMP and high-energy physics is Quantum field theory (QFT). QFT was originally developed to describe the fundamental processes in high-energy physics, but has now become a valuable tool to address problems across physics, in particular, in CMP (Fradkin, 2013; see also, Mustafa, 2023), statistical physics, modern quantum chemistry, and even in

pure mathematics (Folland, 2008). Advances in our understanding of strongly correlated electron systems in CMP such as high-temperature superconductivity and the FQHE have been aided by the QFT. It has facilitated the treatment of spontaneous symmetry broken states, such as superfluids. Interestingly, many of the conceptual developments in CMP have, in return, had a reciprocal impact in QFT. A spectacular example being Nambu's work in dynamical symmetry breaking (Weinberg, 1986; Nambu, 2009) in particle physics, based on the BCS theory of superconductivity.

A glass is a noncrystalline solid obtained by quenching a liquid. It has a liquid-like structure, but a transition from liquid to solid behavior occurs on cooling. It may have one of a continuum of possible ground states that exhibit frozen-in liquid-like disorder. The term “spin glass” was coined by B.R. Coles (Mydosh, 1993) in 1970 for a diluted magnetic material with frozen-in paramagnetic-like spin disorder where the magnetic moments interact with randomly varying positive or negative exchange interactions leading to a multitude of possible ground states with different, random orientations of the spins. As in a normal glass, the energy barriers between the continuum of metastable states prevent it from ever reaching equilibrium. This phase of condensed matter has been an important and productive area of research. Spin-glass models are conceptually simple, but embody sophisticated physics. These models have become a paradigm for the solution of complex optimization problems (Mézard, 2022): much like the undulating flight patterns of starlings around the skies over Rome (Parisi, 2023). After cooling from the paramagnetic phase, the spin glass remains out of equilibrium, and it slowly evolves. This aging phenomenon corresponds to the growth of a “spin-glass order” parameter, whose correlation length can be measured (Joh et al., 1999). A cooling temperature step during aging causes a partial “rejuvenation,” while the “memory” of previous aging is stored and can be retrieved (Refregier et al., 1987; Bouchaud et al., 2001). Many glassy materials present aging, and rejuvenation and memory effects can be found in other cases, but they are usually less pronounced. Numerical simulations of these phenomena are under active investigation using custom-built computers (Baity-Jesi et al., 2023; Vincent, 2023). A general understanding of glassy systems, to which spin glasses bring some special insight, is being pursued. It was realized decades ago that the physics of spin glasses has deep connections with the behavior of complex biological systems. In fact, spin-glass type states in neural network models offer interesting insights into states of high and low brain activity, as observed in mammals (Recio and Torres, 2016). These analogies are potentially useful for applications in fields such as robotics and artificial intelligence (AI) (Andriuschenko et al., 2022).

One of the most spectacular phenomena in CMP, discovered in the last century, was Bose-Einstein condensation (BEC). This macroscopic quantum phenomenon had its genesis in the work of Satyendra Nath Bose (Bose, 1924; Blanpied, 1972; Tomczyk, 2022) (whose name is forever associated with bosons), and has fascinated physicists for decades, ever since the first observation of this exotic state of matter in an ultracold gas of rubidium atoms (Georgescu, 2020). Among the advances made in this field, we highlight only a few: simulation of correlated electron states, such as the FQHE state and a bosonic analog of the Laughlin state, and the famous BEC-BCS crossover from a BEC to a BCS superfluid of weakly bound Cooper pairs, as the interparticle interaction strength is varied. Noteworthy is the recent measurement of the dynamic structure factor in an ultracold Fermi gas of lithium-6 atoms in the “unitary” limit, where a linear phonon mode for low momentum transfer can be clearly discerned (Biss et al., 2022). Perhaps such a method might one day shed light on the Laughlin quasiparticle gap and the collective modes that are still largely unresolved (Chakraborty and Pietiläinen, 1988, 1995; Halperin, 1983; Clark and Maksym, 1989).

Liquid helium, ^4He , and the less common isotope ^3He are unique quantum systems (Volovik, 2009). They remain liquid even at absolute zero temperature, a direct manifestation of Heisenberg's uncertainty principle and zero-point energy. The light mass of helium atoms and their weak interatomic attraction leads to a substantial zero-point kinetic energy and the system remains in the liquid state at ambient pressure. Solidification occurs when a pressure of about 25 MPa is applied. The different quantum statistics of the two helium isotopes (^4He is a boson while ^3He is a fermion) are responsible for the different physical characteristics of the two systems. Microscopic approaches to understand the ground state and low-energy excitations of the liquid state have occupied researchers for many decades (see for example, Ristig and Clark, 1976; Lam et al., 1977). These highly correlated quantum fluids have been established as systems where the efficacies of different many-body theories can be tested (Kallio and Smith, 1977; Lantto et al., 1977). These systems have been described as Ariadne's thread in this Encyclopedia, where the strongly interacting constituent particles are treated by a variety of ingenious theoretical and experimental approaches. Interestingly, liquid helium has been proposed to be a medium to design multiexcitation detectors to probe *dark matter* (Schutz and Zurek, 2016) in the keV mass limit. Although this looks far afield from CMP, the interface between CMP and high-energy particle physics could inspire new horizons in CMP, as discussed earlier.

CMP also has an enormous impact on our daily lives with unceasing technological innovation stemming directly from the advances in CMP research. It is also closely associated with the progress of our understanding of materials science and mechanical, chemical, and electrical engineering that deals with properties of novel materials and devices. As some authors have very aptly pointed out (Chaikin and Lubensky, 1995): The use and understanding of matter in its condensed (liquid or solid) state have gone hand in hand with the advances of civilization and technology since the first use of primitive tools. So important has the control of condensed matter been to man that prehistoric ages—the Stone Age, the Bronze Age, the Iron Age—are named after the material dominating the technology of the time. In fact, modern civilization is entirely dependent on our deep understanding and practical use of materials, old and new: Steel, glass, and concrete have shaped our modern living with comfort, health, longevity, and material wealth. All around us, from a tiny paper clip to giant skyscrapers, from jet planes to modern medicines, and the ubiquitous plastics that are integrated into nearly all aspects of human life, are testaments to our control over the myriad behavior of materials (Miodownik, 2014). Today, a large number of materials are designed by using principles of quantum mechanics (Freeman, 2002).

The Silicon chip that launched the information age is a great example of the effect of CMP on our daily lives. The scaling of transistors down to the nanometer range has enabled them to be embedded in greater numbers in the all-pervasive electronic devices that have transformed every facet of life all around the world. The transition from room-size to pocket-size computers with ever increasing computational power and memory, that occurred in only a few decades, epitomizes the unrelenting progress made in this direction. Advances in nanoscale research have opened the door to exploration of the natural world at the ultra-small scale (Chakraborty, 2022), with the potential to shape our future world.

Quantum dots (QDs), the quasi-zero-dimensional electron systems, are one of the most extensively studied nanostructures in the past three decades. They represent the ultimate reduction in dimensionality of a semiconductor device. Here the electrons are confined (either electrostatically or structurally) in all three directions and occupy spectrally sharp energy levels similar to those found in atoms (Chakraborty, 1999), hence the popular moniker *artificial atoms* (Maksym and Chakraborty, 1990). QDs and other similar nanostructures (Chakraborty, 2003) offer a rich variety of fundamental phenomena that result from manipulation of single electrons (single electronics) or single spins at the nanoscale. The study of interacting electrons in a QD requires large-scale numerical computations involving matrices of dimensions in the millions (“monster matrices”) (Chakraborty and Pietiläinen, 2005; Pietiläinen and Chakraborty, 2006). QDs are also thought to have vast potential for future technological applications. One prominent example being quantum cryptography where the QDs are used in single photon emitters (Nowak et al., 2014), and in single photon detectors (Shields et al., 2000). Quantum cryptography, in turn, forms the basis of the *quantum Internet* (Liao et al., 2018). Other applications include lasers, and spintronics in quantum computing, entertainment industry (Bourzac, 2013), and even in biology (Bruchez and Holz, 2007).

Research in recent years has increasingly revealed that quantum phenomena are also ubiquitous in the natural world (Ball, 2011). They govern how birds are able to navigate around the globe using Earth’s magnetic field or how plants use photosynthesis to harvest sunlight for conversion to chemical energy. All depend on subtle quantum effects that are now coming to light, thereby ushering the topic of quantum biology into CMP. Deoxyribonucleic acid (DNA), the molecule responsible for storage of genetic information in the cells of all living organism, is entrusted with the task of preserving, copying, and transmitting information that are necessary for living beings to grow and function. It is often referred to as the body’s hereditary material as DNA is replicated and transmitted from parents to their offspring. This “molecule of life” was discovered in 1869 by Friedrich Miescher in Tübingen, Germany, who called it “nuclein,” as it was isolated from the nucleus of white blood cells (Dahm, 2005; Thess et al., 2021). It took more than eighty years from that momentous event, to discover that DNA has a right-handed double-helix structure with appropriate base pairing (Watson and Crick, 1953; Klug, 2004). That discovery was so important that it has been compared with the discovery of the atomic nucleus in physics (Frank-Kamenetskii, 1997). Understanding the structure of the atom heralded quantum physics, while understanding of the structure of DNA brought forth the field of molecular biology.

DNA has several remarkable properties that make this molecule a prime candidate for nano-electronic materials (Chakraborty, 2007). These include molecular recognition and the ability to self-assemble via the complementarity of the base sequences on the two strands, which means that DNA can be integrated error-free in current semiconductor technology. DNA can also detect information about its own integrity that can trigger its eventual repair mechanism. All these properties are perfectly suitable for developing nanoscale electronics involving DNA

(Taniguchi and Kawai, 2006). Despite the promise of harnessing biology to realize integrated molecular electronics remains fascinating, much work remains to be done to make it a reality (Braun and Keren, 2004).

Protein molecules play a vital role in all living organisms. They are described as Nature's robots (Tanford and Reynolds, 2001) because for every imaginable task required in a living organism, and for every step of that task, there is a protein designed to carry it out. These proteins are even programmed to know when to turn on or off. Just as the twenty-six letters in the alphabet can spell out hundreds of thousands of words, there are twenty different naturally occurring amino acids that can be combined into many more different proteins than there are atoms in the known universe! Protein's biological function is determined by its unique and native three-dimensional structures that are characteristic of individual proteins (Gomes and Faísca, 2019; Echenique, 2007). The question of how proteins fold to their unique, compact, and highly organized functional states has remained an enduring challenge ("The protein-folding problem") (Chan and Dill, 1993; Dill and MacCallum, 2012; Wolynes and Eaton, 1999). Recently, there has been a tremendous development in this area of research. In November 2020, an AI program called AlphaFold, designed to tackle the problem of protein folding, predicted the three-dimensional structures of almost every protein known to science—about 200 millions in all (Jumper et al., 2021). AlphaFold uses a machine learning methodology to bring together information from preexisting knowledge of protein structures, and other geometric and physical constraints to predict protein structures. While this has been heralded a watershed moment in structural biology (Perrakis and Sixma, 2021), there are many key questions that AlphaFold cannot address yet. These include aspects of protein behavior that cannot be understood from a static structure, such as how proteins respond to their environment or how intrinsically disordered proteins actually are organized. Some authors (Nasser et al., 2021) have likened it to solving a crime story: while AlphaFold presents a snapshot in time, the question about how we get there remains unanswered. Biological systems have developed elaborate mechanisms to ensure that proteins fold correctly, or otherwise, they are detected and degraded before any serious harm can result to the host organism. However, protein misfolding does happen and that misfolding in the cell is linked to an array of diseases, including cancers, cardiovascular disease, type II diabetes, and numerous neurodegenerative diseases, such as Alzheimer's, Parkinson's, and Huntington's disease. NMR spectroscopy has been an important technique to study protein folding where valuable insights are gained into many aspects of the folding process (Jane Dyson and Wright, 1996).

In this Encyclopedia, we strive to present a taste of all the developments in CMP described above (and much more), written by experts in the field. We are keenly aware that many important and interesting topics are not covered here. However, that is not for want of trying. As some authors had rightly pointed out (Hoddeson, 1992): The field is huge and varied and lacks the unifying features beloved of historians, neither a single hypothesis or set of basic equations underpin the field, as in quantum mechanics or relativity theory, nor a single spectacular and fundamental discovery such as uranium fission for nuclear technology or the structure of DNA for molecular biology. CMP owes what unity it has simply to a common concern with solid and liquid materials. This encompasses such a large range of theories and methods that the field resembles a confederation of interest groups rather than a single entity. Clearly, the task of collecting everything in one place is a monumental endeavor, but we do hope that our compilation of a large number of chapters in this five-volume work, covering a broad range of in-depth descriptions of varied phenomena in CMP will be a treasured source of facts and ideas for the community.

It is undeniably true that there would have been no Encyclopedia without the extraordinary contributions of the large number of authors whose valuable time and efforts brought this project to fruition. My sincere thanks to all of them. I also wish to extend my deep appreciation to the staff at Elsevier for their skillful handling of this huge project. The cover image was created by Hong-Yi Chen from National Taiwan Normal University. The image below was created by Elisabetta Collini, one of the authors. My deepest appreciation to them for taking the time to do this work. Finally, my sincere thanks to the Section editors, Vladimir Fomin, Ana Sanchez, Roberto Raimondi, Hideo Aoki, Rudolf Römer, and Robert Blick for the effort they all expended, that has contributed to the success of this venture. Special thanks go to Vladimir Fomin and Ana Sanchez for securing a large share of the chapters and for their enduring help in providing valuable advice and support to bring the project to fruition. Thanks are also due to many of my friends and colleagues, in particular, Michael Coey, Jürg Fröhlich, Sinéad Griffin, Peter Maksym, Eric Vincent, and Jakob Yngvason for their careful and critical reading of the introduction.

LIST OF CONTRIBUTORS FOR VOLUME 5

P Ambs

Université de Haute Alsace, ENSISA, Mulhouse, France

Vadym Apalkov

Department of Physics and Astronomy, Georgia State University, Atlanta, GA, United States

Maurizio Artoni

European Laboratory for Nonlinear Spectroscopy (LENS), Sesto Fiorentino, Firenze, Italy; Department of Engineering and Information Technology, Brescia University, Brescia, Italy; Istituto Nazionale di Ottica (INO-CNR), Firenze, Italy

SP Baker

Cornell University, Ithaca, NY, USA

Marcello Baricco

Department of Chemistry and NIS-INSTM, University of Turin, Turin, Italy

Franco Bassani[†]

WA Bassett

Cornell University, Ithaca, NY, USA

Jean Bellissard

School of Mathematics, Georgia Institute of Technology, Atlanta, GA, United States

TR Bieler

Michigan State University, East Lansing, MI, USA

K Binder

Johannes Gutenberg Universität Mainz, Mainz, Germany

C Brezinski

Université des Sciences et Technologies de Lille, Villeneuve d'Ascq, France

Jaehee Cho

Chonbuk National University, Jeonju, South Korea

Katerina A Christofidou

Department of Materials Science and Engineering, University of Sheffield, Sheffield, United Kingdom

TW Clyne

University of Cambridge, Cambridge, UK

MM Coleman

The Pennsylvania State University, University Park, PA, USA

P Colombo

University of Bologna, Bologna, Italy

KP Constant

Iowa State University, Ames, IA, USA

I Cristiani

Università di Pavia, Pavia, Italy

N Daldosso

Università di Trento, Povo (Trento), Italy

M de Boissieu

Université Grenoble Alpes, CNRS, Grenoble INP-UGA, SIMaP, Grenoble, France

V Degiorgio

Università di Pavia, Pavia, Italy

Natasha Dropka

Leibniz-Institut für Kristallzüchtung (IKZ), Berlin, Germany

EN Economou

University of Crete, Heraklion, Greece

S Elsheikhi

University of Benghazi, Benghazi, Libya; University of Tokyo, Tokyo, Japan

DG Eskin

Brunel University London, Uxbridge, United Kingdom

C Ewels

Nantes Université, CNRS, Institut des Matériaux de Nantes Jean Rouxel, IMN, Nantes, France

JS Faulkner

Center for Biological and Materials Physics, Department of Physics, Florida Atlantic University, Boca Raton, FL, United States

[†]Deceased.

Michael Ferry
School of Materials Science and Engineering, The University of New South Wales, Sydney, NSW, Australia

Mike W Finnis
Department of Materials and Department of Physics, The Thomas Young Centre, Imperial College London, London, United Kingdom

W Beall Fowler
Lehigh University, Bethlehem, PA, United States

J Freudenberger
Leibniz IFW Dresden, Department of Metal Physics, Institute for Complex Materials, Dresden, Germany; TU Bergakademie Freiberg, Institute of Materials Science, Freiberg, Germany

J Friedrich
Fraunhofer Institute IISB, Erlangen, Germany

H Fujita
University of Tokyo, Tokyo, Japan

Z Gaburro
Università di Trento, Povo (Trento), Italy

Nathaniel P Gallop
Department of Physics, University of Warwick, Coventry, United Kingdom

AM Glazer
University of Oxford, Oxford, United Kingdom

JB Goodenough
University of Texas at Austin, Austin, TX, USA

O Gourdon
Iowa State University, Ames, IA, USA

D Gout
Iowa State University, Ames, IA, USA

Kevin-Peter Gradwohl
Leibniz-Institut für Kristallzüchtung (IKZ), Berlin, Germany

Uwe Grimm
Department of Mathematics and Statistics, The Open University, Walton Hall, Milton Keynes, United Kingdom

Giorgio Guizzetti
Dipartimento di Fisica, Università degli Studi di Pavia, Pavia, Italy

Th Hahn
Institut für Kristallographie, RWTH Aachen, Aachen, Germany

A Harju
Aalto University, Espoo, Finland

Naoki Haruta
Fukui Institute for Fundamental Chemistry, Kyoto University, Kyoto, Japan

WF Hosford[†]

J-P Huignard
Thales Research & Technology, Palaiseau, France

Stuart JC Irvine
Swansea University, Wales, United Kingdom

T Janssen
University of Nijmegen, Nijmegen, The Netherlands

Shin-Woong Kang
Department of Nano Convergence Engineering, Jeonbuk National University, Jeonju, Korea

MI Katsnelson
Radboud University Nijmegen, Nijmegen, The Netherlands

James R Kermode
Warwick Centre for Predictive Modelling, School of Engineering, University of Warwick, Coventry, United Kingdom

Jong Kyu Kim
Pohang University of Science and Technology, Pohang, South Korea

H Klapper
Mineralogisch-Petrologisches Institut, Universität Bonn, Bonn, Germany

Robert Kudrawiec
Department of Semiconductor Materials Engineering, Faculty of Fundamental Problems of Technology, Wrocław University of Science and Technology, Wrocław, Poland

Satyendra Kumar
Division for Research and Economic Development, and Department of Physics, University at Albany, Albany, NY, United States

GC La Rocca
NEST, Scuola Normale Superiore, Pisa, Italy

S Latil
CEA, IRAMIS, SPEC, GMT, Gif-sur-Yvette, France

Ron Lifshitz
Raymond and Beverly Sackler School of Physics & Astronomy, Tel Aviv University, Tel Aviv, Israel; School of Mathematics, University of Leeds, Leeds, United Kingdom

B Loiseaux
Thales Research & Technology, Palaiseau, France

[†]Deceased.

DA Lyashenko
Department of Physics and Mathematics, University of Eastern Finland, Joensuu, Finland

AE Markaki
University of Cambridge, Cambridge, UK

Paolo Mataloni
Physics Department, Sapienza University of Rome, Rome, Italy

F Mezei
Hahn-Meitner-Institut, Berlin, Germany

GJ Miller
Iowa State University, Ames, IA, USA

Rebecca L Milot
Department of Physics, University of Warwick, Coventry, United Kingdom

Eduard V Monaico
National Center for Materials Study and Testing, Technical University of Moldova, Chisinau, Republic of Moldova

Uwe Mueller
Macromolecular Crystallography, Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Berlin, Germany

Jian-Feng Nie
Monash University, Melbourne, VIC, Australia

PC Painter
The Pennsylvania State University, University Park, PA, USA

Lukas Palatinus
Institute of Physics of the CAS, Prague, Czechia

Maddalena Patrini
Dipartimento di Fisica, Università degli Studi di Pavia, Pavia, Italy

L Pavesi
Università di Trento, Povo (Trento), Italy

Jun Peng
Center for Hybrid Nanostructures, Universität Hamburg, Hamburg, Germany

B Raveau
Laboratoire de Cristallographie, ISMRA, Caen, France

Giancarlo Ruocco
Center for Life Nano Science @Sapienza, Istituto Italiano di Tecnologia, Roma, Italy; Dipartimento di Fisica, Università di Roma "La Sapienza", Roma, Italy

JS Rutherford
National University of Science and Technology, Bulawayo, Zimbabwe

Federico Scaglione
Department of Chemistry and NIS-INSTM, University of Turin, Turin, Italy

Walter Schirmacher
Institut für Physik, Universität Mainz, Mainz, Germany; Center for Life Nano Science @Sapienza, Istituto Italiano di Tecnologia, Roma, Italy

Michael Schreiber
Institut für Physik, Technische Universität Chemnitz, Chemnitz, Germany

E Fred Schubert
Rensselaer Polytechnic Institute, Troy, NY, USA

Caspar Schwalbe
MTU Aero Engines AG, Munich, Germany

Gautam Singh
Department of Applied Physics, Amity Institute of Applied Sciences, Amity University Uttar Pradesh, Noida, India

CM Soukoulis
Iowa State University, Ames, IA, USA

Riccardo Spagna
Institute of Crystallography—CNR, Montelibretti, Italy

EA Starke Jr.
University of Virginia, Charlottesville, VA, United States

M Strangwood
University of Warwick, Coventry, West Midlands, United Kingdom

J-B Suck
Chemnitz University of Technology, Chemnitz, Germany

Yu P Svirko
Department of Physics and Mathematics, University of Eastern Finland, Joensuu, Finland

Ion M Tiginyanu
Academy of Sciences of Moldova, Chisinau, Republic of Moldova; National Center for Materials Study and Testing, Technical University of Moldova, Chisinau, Republic of Moldova

L Tikana
Deutsches Kupferinstitut Berufsverband e.V., Düsseldorf, Germany

Y Toyozawa
University of Tokyo, Tokyo, Japan

RM Trevino
Michigan State University, East Lansing, MI, USA

V Vitek
University of Pennsylvania, Philadelphia, PA, USA

DA Walko

Argonne National Laboratory, Argonne, IL, USA

Manfred S Weiss

*Macromolecular Crystallography, Helmholtz-Zentrum
Berlin für Materialien und Energie GmbH, Berlin,
Germany*

DJ Willock

*Cardiff Catalysis Institute, School of Chemistry, Cardiff
University, Cardiff, United Kingdom*

Kimihisa Yamamoto

*Institute of Innovative Research, Tokyo Institute of
Technology, Tokyo, Japan*

I Yasui

University of Tokyo, Tokyo, Japan

An-Chou Yeh

*Department of Materials Science and Engineering,
National Tsing Hua University, Hsinchu, Taiwan, ROC;
High Entropy Materials Center, National Tsing Hua
University, Hsinchu, Taiwan, ROC*

Jien-Wei Yeh

*Department of Materials Science and Engineering,
National Tsing Hua University, Hsinchu, Taiwan, ROC;
High Entropy Materials Center, National Tsing Hua
University, Hsinchu, Taiwan, ROC*

Hung Yen

*Department of Materials Science and Engineering,

Hamburg, Germany*

C Zweben

Zweben Consulting, Newtown Square, PA, United States

CONTENTS OF VOLUME 5

Magnetic point groups and space groups <i>Ron Lifshitz</i>	1
Crystal structure <i>AM Glazer</i>	11
Periodicity and lattices <i>JS Rutherford and AM Glazer</i>	17
Crystal structure determination <i>Lukas Palatinus and Riccardo Spagna</i>	29
Macromolecular crystallography <i>Uwe Mueller and Manfred S Weiss</i>	41
Point groups <i>H Klapper and Th Hahn</i>	49
Space Groups <i>T Janssen</i>	61
Crystal Symmetry <i>Th Hahn and H Klapper</i>	69
Crystal optics <i>DA Lyashenko and Yu P Svirko</i>	80
Holography <i>P Ambs, J-P Huignard, and B Loiseaux</i>	88
Sum rules and Kramers-Kronig relations in linear and nonlinear optics <i>Franco Bassani</i>	105
Semiconductor optics <i>GC La Rocca</i>	118
Ultrafast optics of topological materials <i>Vadym Apalkov</i>	128
Electromagnetically induced transparency <i>Maurizio Artoni</i>	138
Optical properties of materials <i>Giorgio Guizzetti and Maddalena Patrini</i>	150
Photon statistics and coherence theory <i>Paolo Mataloni</i>	167
Point defects <i>W Beall Fowler</i>	184
Methods for bulk growth of inorganic crystals <i>J Friedrich</i>	190

Crystal binding (interatomic forces): Ionic bonding and crystals <i>Mike W Finnis and James R Kermode</i>	208
Crystal binding (interatomic forces): Metallic bonding and crystals <i>DJ Willock</i>	217
Crystal growth, bulk: Theory and models <i>Natasha Dropka and Kevin-Peter Gradwohl</i>	231
Film growth and epitaxy methods <i>Stuart JC Irvine</i>	248
Thin Films, Mechanical Behavior of <i>SP Baker</i>	261
Electronic and transport properties of aperiodic media <i>Jean Bellissard</i>	269
Lattice dynamics: Aperiodic crystals <i>J-B Suck</i>	278
Electronic structure of quasicrystals <i>Uwe Grimm and Michael Schreiber</i>	290
Vibrational excitations in disordered solids <i>Walter Schirmacher and Giancarlo Ruocco</i>	298
Atomic structure of quasicrystals <i>M de Boissieu</i>	318
Materials: Composites <i>C Zweben</i>	333
Self-organized porous semiconductor compounds <i>Ion M Tiginyanu and Eduard V Monaico</i>	350
Structures: Liquid crystals <i>Gautam Singh, Shin-Woong Kang, and Satyendra Kumar</i>	375
Highly Porous Metals and Ceramics <i>AE Markaki, P Colombo, and TW Clyne</i>	390
Dislocations <i>V Vitek</i>	404
Lattice Dynamics: Anharmonic Effects <i>MI Katsnelson</i>	411
Ceramic Materials <i>KP Constant</i>	416
Polymers, History of <i>MM Coleman and PC Painter</i>	424
Neutrons and Neutron Scattering, History of <i>F Mezei</i>	429
Ceramics, History of <i>I Yasui</i>	437
Porous Silicon <i>Z Gaburro, N Daldossoh, and L Pavesi</i>	442
Electronic states of semiconductor compounds and alloys <i>Robert Kudrawiec</i>	453
Intermetallic Compounds, Electronic States of <i>O Gourdon, D Gout, and GJ Miller</i>	469

Transition-Metal Compounds, Electronic and Magnetic Properties of <i>JB Goodenough</i>	485
Micromechanical Devices and Systems <i>H Fujita and S Elsheikhi</i>	504
Alloys: Overview <i>Federico Scaglione and Marcello Baricco</i>	511
Alloys: Iron <i>Michael Ferry</i>	522
Alloys: Steel <i>M Strangwood</i>	533
Alloys: Magnesium <i>Jian-Feng Nie</i>	549
Electronic structure: Impurity and defect states in metals and alloys <i>JS Faulkner</i>	565
Alloys: Aluminum <i>EA Starke Jr. and DG Eskin</i>	573
Alloys: The superalloys <i>Katerina A Christofidou and Caspar Schwalbe</i>	583
Alloys: Copper <i>J Freudenberger, L Tikana, and WF Hosford</i>	601
Alloys: Titanium <i>TR Bieler, RM Trevino, and L Zeng</i>	635
High-entropy alloys: An overview on the fundamentals, development, and future perspective <i>Hung Yen, An-Chou Yeh, and Jien-Wei Yeh</i>	647

Abstract

The spatial symmetry of matter—including finite objects like molecules or atomic clusters, and extended objects like periodic or aperiodic crystals—is described using point groups and space groups. Magnetic point groups and space groups are the simplest extension of this description, to matter whose atomic constituents possess a property that can take one of two possible values, like the “up” or “down” orientations of a magnetic moment, or a spin. Magnetic groups—also known as antisymmetry groups, Shubnikov groups, Heesch groups, Opechowski-Guccione groups, as well as dichromatic, 2-color, or simply black-and-white groups—are here defined, and their structure and notation explained, while providing some pedagogical examples of their enumeration. The resulting magnetic selection rules, or extinctions, in neutron diffraction experiments are discussed. Further extensions to color groups and spin groups are briefly described.

Key points

- The spatial symmetry of matter is described using point groups and space groups. Magnetic point groups and space groups are the simplest extension of this description to matter whose atomic constituents possess a property that can take one of two possible values.
- Magnetic point groups are used to describe the point symmetry of magnetically ordered objects—whether these objects are finite, like molecules or clusters, or extended, like periodic or aperiodic crystals. They are defined below, and their structure and notation explained, while providing some pedagogical examples of their enumeration.
- Magnetic space groups are used to describe the full magnetic symmetry of extended magnetically ordered, periodic or aperiodic, crystals. They are also defined below, and their structure and different notations explained, while providing some pedagogical examples of their enumeration.
- Magnetic groups are also known in the literature as antisymmetry groups, Shubnikov groups, Heesch groups, Opechowski-Guccione groups, as well as dichromatic, 2-color, or simply black-and-white groups.
- One of the most direct physical consequences of having magnetic symmetry in crystals, is the systematic extinction of magnetic Bragg peaks in neutron diffraction patterns. These can be calculated directly from the magnetic space group.
- Magnetic groups are naturally generalized to cases where the property of interest is not limited to having one of only two possible values. The common extensions are to color groups with more than just two distinct colors, or to spin groups, where the orientation of the magnetic moments can vary continuously.

[☆]*Change History:* September 2022. R Lifshitz updated the chapter.

¹The symmetry of nonmagnetic periodic crystals is discussed in numerous crystallography textbooks. For a nice informal introduction see Senechal (1990). For a detailed overview of the symmetry of nonmagnetic quasiperiodic crystals see Mermin (1992); for a more elementary introduction see Lifshitz (1996).

Introduction

Magnetic groups—also known as antisymmetry groups, Shubnikov groups, Heesch groups, Opechowski-Guccione groups, as well as dichromatic, 2-color, or simply black-and-white groups—are the simplest extension to standard point group and space group theory.¹ They allow directly to describe, classify, and study the physical consequences of the symmetry of materials, characterized by having a certain added property that locally can take one of two possible values. These may include finite objects like molecules or atomic clusters, as well as extended periodic or aperiodic crystals. To do so, one introduces a single additional symmetry operation of order two that interchanges the two possible values everywhere. This operation can be applied to the material along with any of the standard point group or space group operations, and is commonly denoted by adding a prime to the original operation. Thus, any rotation g followed by this external operation is denoted by g' .

We begin in Section “Two-valued properties” with a few typical examples of this two-valued property, some of which are illustrated in Fig. 1. In Section “Magnetic point groups” we discuss the notion of a magnetic point group, followed by a discussion on magnetic space groups in Section “Magnetic space groups.” In Section “Extinctions in neutron diffraction of antiferromagnetic crystals” we describe one of the most direct physical consequences of having magnetic symmetry in crystals, which is the systematic extinction of magnetic Bragg peaks in neutron diffraction patterns. We finish in Section “Conclusion: Generalizations of magnetic groups” by briefly describing the generalization of magnetic point groups and space groups to cases where the property of interest is not limited to having one of only two possible values.

Two-valued properties

Let us begin by considering the structure of crystals of the cesium chloride (CsCl) type. In these periodic crystals the atoms are located on the sites of a body-centered cubic (bcc) lattice. Atoms of one type are located on the simple cubic lattice formed by the corners of the cubic cells, and atoms of the other type are located on the simple cubic lattice formed by the body centers of the cubic cells. The parent bcc lattice is bipartitioned in this way into two identical sublattices, related by a half body-diagonal translation. One may describe the symmetry of the cesium chloride structure as having a simple cubic lattice of ordinary translations, with a basis containing one cesium and one chlorine atom. Alternatively, one may describe the symmetry of the crystal as having twice as many translations per unit volume, forming a bcc lattice, half of which are primed to indicate that they are followed by an operation that exchanges the chemical identities of the two types of atoms. A similar situation occurs in crystals whose structure is of the sodium chloride (NaCl) type in which a simple cubic lattice is bipartitioned into two identical face-centered cubic (fcc) sublattices.

Another typical example is the orientational ordering of magnetic moments or spins, electric dipole moments, or any other tensorial property associated with each site in a crystal. Adopting the language of spins, if these can take only one of two possible orientations—“up” and “down”—as in simple Ising antiferromagnets, we have the same situation as above, with the two spin orientations replacing the two chemical species of atoms. In the case of spins, the external prime operation is a so-called antisymmetry operation that reverses the directions of the spins. Physically, one may think of using the operation of time inversion to reverse the directions of all the spins without affecting anything else in the crystal.

Fig. 1 Several realizations of the simple one-dimensional magnetic space group $p_p\bar{1}$ (or $p_p m$). Note that the number of symmetry translations is doubled if one introduces an operation e' that interchanges the two possible values of the property, associated with each crystal site. Also note that spatial inversion $\bar{1}$ (or mirror reflection m) can be performed without a prime on each crystal site, and with a prime ($\bar{1}'$ or m') between every two sites. (a) An abstract representation of the two possible values as the two colors—black and white. The operation e' is the nontrivial permutation of the two colors. (b) A simple antiferromagnetic arrangement of spins. The operation e' is time inversion which reverses the directions of the spins. (c) A ferromagnetic arrangement of two types of spins, where e' exchanges them as in the case of two colors. (d) A 1-dimensional version of salt, where e' exchanges the chemical identities of the two atomic species. (e) A function $S(x)$ whose overall sign changes by the application of the operation e' . Enc. of Cond. Mat. Phys. (Elsevier, 2005), p. 219.

As a final example, consider a periodic or quasiperiodic scalar function of space, $f(\mathbf{r})$, as in Fig. 1(e), whose mean value is zero. One can often extend the point group or space group, describing the symmetry of such functions, by introducing an external prime operation that flips the sign of $f(\mathbf{r})$, by multiplying it by -1 .

For the sake of clarity we shall adopt the picture of up-and-down spins, and the use of time inversion to exchange them, for the remaining of our discussion, but some terminology from the color description will be used when helpful. It should be emphasized, though, that most of what we say here—perhaps excluding the discussion of extinctions in Section “Extinctions in neutron diffraction of antiferromagnetic crystals”—applies equally to any other two-valued property. We describe the magnetic crystal using a scalar spin-density field $S(\mathbf{r})$ whose magnitude gives the magnitude of an atomic magnetic moment, or some coarse-grained value of the magnetic moment, at position $\mathbf{r}$. The sign of $S(\mathbf{r})$ gives the direction of the spin—a positive sign for “up” spins and a negative sign for “down” spins. The function $S(\mathbf{r})$ can be a discrete set of positive or negative delta functions, defined on the crystal sites as in Fig. 1(b), or a continuous spin-density field as in Fig. 1(e).

Magnetic point groups

A d -dimensional *magnetic point group* G_M is a subgroup of $O(d) \times 1'$, where $O(d)$ is the orthogonal group of d -dimensional rotations, and $1' = \{e, e'\}$ is the time inversion group containing the identity e and the time inversion operation e' . Note that we use the term “rotation” to refer to proper as well as improper rotations, such as mirrors and the spatial inversion.

Three types of subgroups exist: (1) The most trivial subgroups are simply the ordinary nonmagnetic point groups, containing rotations alone, with no use of the time-inversion operation; (2) Slightly less trivial subgroups are those in which all rotations appear both with and without time-inversion; and (3) Nontrivial subgroups are those where exactly half of the rotations are followed by time inversion and the other half are not. In the context of color symmetry, these three types of subgroups are often called *colorless*, *gray*, and *black-and-white* groups, respectively, a terminology which will become clear shortly.

More formally, if G is any ordinary nonmagnetic point group, namely, any subgroup of $O(d)$, it can be used to construct at most three types of magnetic point groups G_M , forming its so-called *magnetic superfamily*, as follows:

1. $G_M = G$, so that no rotation is followed by time inversion. It is an ordinary nonmagnetic point group.
2. $G_M = G \times 1'$, so that each rotation in G appears in G_M once by itself and once followed by time inversion. Note that in this case $e' \in G_M$.
3. $G_M = H + g'H$, where H is a subgroup of index 2 in G , and g is a particular element of G which is not in H , so that $G = H + gH$. Thus, exactly half of the rotations in G , which belong to its subgroup H , appear in G_M by themselves, and the other half, belonging to the coset $gH = \{gh | h \in H\}$, are followed by time inversion. Note that in this case $e' \notin G_M$.

Enumeration of magnetic point groups is thus straightforward. Any ordinary point group G —that is, any subgroup, usually finite, of $O(d)$ —is trivially a colorless magnetic point group of type 1, and along with the time inversion operation generates a gray magnetic point group of type 2, denoted as $G1'$. One then lists all distinct subgroups H of index 2 in G , if there are any, to construct nontrivial black-and-white magnetic point groups of type 3. These are denoted either by the group-subgroup pair $G(H)$, or as we shall do here, by using the International (Hermann-Mauguin) symbol for G , while adding a prime to those elements in the symbol that do not belong to the subgroup H and are therefore followed by time inversion.

A simple way of finding all the subgroups H of index 2 in G is to pick a set of generators for G , and consider all combinations in which each generator of *even* order is either primed or unprimed. The resulting black-and-white point groups then need to be checked for equivalence as conjugate subgroups of $O(d) \times 1'$ and grouped into so-called *magnetic geometric crystal classes*. As an example, we enumerate in Table 1 the distinct classes of magnetic point groups in the orthorhombic crystal system. Tables of all

Table 1 Orthorhombic magnetic point groups.

<i>Colorless</i>	<i>Gray</i>	<i>Black & White</i>
222	2221'	2'2'2
<i>mm</i> 2	<i>mm</i> 21'	<i>m'</i> <i>m'</i> 2'; <i>m'</i> <i>m'</i> 2
<i>mmm</i>	<i>mmm</i> 1'	<i>mmm</i> 1'; <i>m'</i> <i>m'</i> <i>m'</i> ; <i>m'</i> <i>m'</i> <i>m'</i>

Magnetic point groups in the orthorhombic crystal system. Each row lists the magnetic superfamily of one of the ordinary, or colorless, orthorhombic point groups G , listed in the first column. The second column lists the trivial gray groups $G1'$. To enumerate the black-and-white point groups—listed in the third column by their International (Hermann-Mauguin) symbol—one considers all distinct subgroups H of index 2 in G . For example, the orthorhombic point group $G = 222 = \{e, 2_x, 2_y, 2_z\}$ has three subgroups of index 2, $H_1 = \{e, 2_z\}$, $H_2 = \{e, 2_y\}$, and $H_3 = \{e, 2_x\}$. This gives three corresponding black-and-white point groups—22'2', 2'22', and 2'2'2—in which two twofold rotations are primed and the third is not. As these groups are all equivalent as conjugate subgroups of $O(3) \times 1'$, they are merely different settings of just a single geometric crystal class of black-and-white point groups. On the other hand, taking the two mirrors as generators of the orthorhombic point group $G = mm2 = \{e, m_x, m_y, 2_z\}$, one can associate time inversion with just a single one of them (in which case the twofold rotation is also primed), or with both. This gives three black-and-white point groups—*m'* *m'*2', *mm'*2', and *m'* *m'*2—of which only the first two are equivalent, yielding two geometric crystal classes of black-and-white point groups. In total there are $3 + 3 + 6 = 12$ types of orthorhombic magnetic point groups in three dimensions.

magnetic point groups that are compatible with periodic crystals—and therefore restricted to rotational axes of order 1, 2, 3, 4, and 6—appear in the original work by Shubnikov (1964) and in the more recent book by Litvin (2013), while Lifshitz (1997) provides the extension of these tables to all magnetic point groups in 2- and in 3-dimensions with rotational axes of arbitrary order.

Black-and-white magnetic point groups (type 3) can be used to describe the point symmetry of finite objects, as described in Section “Magnetic point groups of finite objects”, as well as that of infinite crystals, as described in Section “Magnetic point groups of crystals.” Trivial, or colorless, magnetic point groups (type 1), equivalent to ordinary nonmagnetic point groups, are usually mentioned only for the sake of completeness. Strictly speaking, they can be said to describe the symmetry of ferromagnetic materials with no spin-orbit coupling. Gray magnetic point groups (type 2) can be used to describe the point symmetry of infinite crystals, but because they include ϵ' as a symmetry element they cannot, strictly speaking, be used to describe the symmetry of finite magnetic or two-colored objects, as explained below.

Magnetic point groups of finite objects

The magnetic symmetry of a finite object, such as a molecule or a cluster containing an equal number of two types of spins, can be described by a magnetic point group. We say that a primed or unprimed rotation from $O(d) \times 1'$ is in the magnetic point group G_M of a finite object in d dimensions, if it leaves the object invariant. Clearly, only black-and-white magnetic point groups (type 3 in the list above), can describe the symmetry of finite magnetically ordered structures. This is because time inversion ϵ' changes the orientations of all the spins, and therefore cannot leave the object invariant unless it is accompanied by a nontrivial rotation. For this reason, point groups of type 2 are often called “gray” groups, as they describe the symmetry of “gray” objects which remain invariant under the exchange of black and white. For a comprehensive discussion on the magnetic symmetry of finite objects, see the original work by Shubnikov (1964).

Magnetic point groups of crystals

The magnetic point group of a d -dimensional magnetically ordered *periodic crystal*, containing an equal number of up and down spins, is defined as the set of primed or unprimed rotations from $O(d) \times 1'$ that leave the crystal *invariant to within a translation*. The magnetic point group of a crystal can be either of the first or of the second types listed above. It is a gray group (of type 2) if time inversion by itself leaves the crystal invariant to within a translation. In this case, any rotation in the magnetic point group can be performed either with or without time inversion. If time inversion cannot be combined with a translation to leave the crystal invariant, the magnetic point group is black and white (of type 3), in which case half of the rotations are performed without time inversion and the other half with time inversion.

Fig. 2(a) shows an example of a magnetically ordered periodic crystal, with tetragonal symmetry, given by the magnetic point group $G_M = 4mm1'$, which is of type 2. Here, time inversion can be followed by a translation to leave the crystal invariant. Fig. 2

Fig. 2 Periodic antiferromagnets. (a) Tetragonal crystal with a gray magnetic point group $G_M = 4mm1'$, and a class-equivalent magnetic space group $p_4Am\bar{m}$ (also denoted $p_4Am\bar{m}$). Time inversion leaves this tetragonal antiferromagnetic periodic crystal invariant to within a translation. (b) Hexagonal crystal with a black-and-white magnetic point group $G_M = 6'mm'$, and a lattice-equivalent magnetic space group $p6'mm'$. Time inversion does not leave this hexagonal antiferromagnetic periodic crystal invariant to within a translation. Enc. of Cond. Mat. Phys. (Elsevier, 2005), p. 222.

(b) shows an example of a periodic crystal with hexagonal symmetry, given by the magnetic point group $G_M = 6' mm'$, which is of type 3. Note that all right-side-up triangles contain a blue circle (spin up) and all up-side-down triangles contain a green circle (spin down). Time inversion, exchanging the two types of spins, cannot be combined with a translation to recover the original crystal. Time inversion must be combined with a nontrivial operation—such as mirrors of the horizontal type or odd powers of the sixfold rotation—that interchanges the two types of triangles to recover the original crystal. Note that mirrors of the vertical type (the first m in the International symbol) leave the crystal invariant without requiring time inversion, and are therefore unprimed in the symbol.

More generally, the magnetic point group of a d -dimensional magnetically ordered crystal—whether periodic or not²—is defined as the set of primed or unprimed rotations from $O(d) \times 1'$ that leave the crystal *indistinguishable*. This means that the rotated and unrotated crystals contain the same spatial distributions of finite clusters of spins of arbitrary size. The two crystals are thus statistically the same, though not necessarily identical to within a translation. Only for the special case of periodic crystals does the notion of *indistinguishability* reduce to invariance to within a translation.

Fig. 3 shows two aperiodic examples, analogous to the two periodic examples of Fig. 2. Fig. 3(a) shows an octagonal quasicrystal with magnetic point group $G_M = 8 mm1'$. One can see that time inversion rearranges the spin clusters in the crystal but they all still appear in the crystal with the same spatial distribution. This is because any finite spin cluster and its time-reversed image appear in the crystal with the same spatial distribution. Fig. 3(b) shows a decagonal quasicrystal with magnetic point group $G_M = 10' m' m$. In this case, time inversion does not leave the crystal indistinguishable. It must be combined either with odd powers of the 10-fold rotation, or with mirrors of the vertical type, to produce a crystal with the same spatial distributions of finite spin clusters as in the original one.

Magnetic space groups

The full symmetry of a magnetically ordered crystal, described by a set of “up” and “down” spins, or a coarse-grained scalar spin-density field $S(\mathbf{r})$, is given by its magnetic space group $\mathcal{G}_M$. We said that the magnetic point group G_M is the set of primed or unprimed rotations that leave a periodic crystal invariant to within a translation, or more generally, leave a quasiperiodic crystal indistinguishable. We still need to specify the distinct sets of translations $\mathbf{t}_g$ or $\mathbf{t}_{g'}$ that can accompany the rotations g or g' in a periodic crystal to leave it invariant, or provide the more general characterization of the nature of the indistinguishability in the case of quasicrystals, as explained below.

Fig. 3 Antiferromagnetic quasicrystals. (a) Octagonal quasicrystal with a gray magnetic point group $G_M = 8 mm1'$, and a class-equivalent magnetic space group $p_7 8mm$. Time inversion leaves this octagonal antiferromagnetic quasicrystal indistinguishable. (b) Decagonal quasicrystal with a black-and-white magnetic point group $G_M = 10' m' m$, and a lattice-equivalent magnetic space group $p10' m' m$. Time inversion does not leave this decagonal antiferromagnetic quasicrystal indistinguishable. Enc. of Cond. Mat. Phys. (Elsevier, 2005), p. 223.

²Of particular relevance is the generalization from periodic crystals to the wider category of *quasiperiodic crystals*. Quasiperiodic crystals that are explicitly aperiodic are called *quasicrystals*. For proper definitions and detailed terminology, see, for example Lifshitz (2003, 2007, 2011).

Magnetic symmetry of periodic crystals

One can take any ordinary nonmagnetic space group $\mathcal{G}$ of a periodic crystal, also called a Fedorov-Schönflies space group, and form its *magnetic superfamily*. As in the case of magnetic point groups, there are two trivial magnetic space-group types:

- I. *Colorless magnetic space groups*: These are ordinary nonmagnetic Fedorov-Schönflies space groups, where $\mathcal{G}_M = \mathcal{G}$.
- II. *Gray magnetic space groups*: Here $\mathcal{G}_M = \mathcal{G} \times 1'$ (denoted simply as $\mathcal{G}1'$), implying that every operation in $\mathcal{G}$ can be applied with or without being followed by time inversion.

Nontrivial black-and-white magnetic space groups take the form

$$\mathcal{G}_M = \mathcal{H} + (g'|\mathbf{t}_g)\mathcal{H}, \quad (1)$$

where $\mathcal{H}$ is a subgroup of index 2 in $\mathcal{G}$, and $(g'|\mathbf{t}_g)$ denotes a primed rotation g' , possibly followed by a translation $\mathbf{t}_g$. They are divided into two types, depending on their magnetic point groups G_M :

- III. *Lattice-equivalent magnetic space groups*: If the magnetic point group G_M is black and white (of type 3), the point group H of $\mathcal{H}$ is a subgroup of index 2 of the point group G of $\mathcal{G}$, and the Bravais lattices of $\mathcal{G}$ and $\mathcal{H}$ are the same. Rotations in G that are not in H must be combined with time inversion to leave the magnetic crystal invariant to within a translation.
- IV. *Class-equivalent magnetic space groups*: If the magnetic point group G_M is gray (of type 2), with all rotations in G appearing with and without time inversion, the point groups of $\mathcal{G}$ and $\mathcal{H}$ are the same, and the Bravais lattice T of $\mathcal{H}$ is a sublattice of index 2 of the Bravais lattice T_0 of $\mathcal{G}$. Translations in T_0 that are not in T must be combined with time inversion to leave the magnetic crystal invariant.

Enumeration of lattice-equivalent magnetic space-group types is straightforward. Given an ordinary nonmagnetic space group $\mathcal{G}$, simply consider all distinct subgroups H of index 2 of the point group G of $\mathcal{G}$, as explained in Section “Magnetic point groups.” The only additional consideration is that there may be more than one way to orient the subgroup H relative to the Bravais lattice of translations that leave the periodic crystal invariant. Take, for example, the magnetic point group $m'm'2'$, which as explained in Table 1, is equivalent to $mm'2'$. Consequently, on a primitive orthorhombic lattice, $Pm'm'2'$ and $Pmm'2'$ are two different settings of the same magnetic space-group type. But, on an A-centered orthorhombic lattice, where the x - and y -axes are no longer equivalent, one needs to consider both options as distinct groups. We say that the two distinct magnetic space-group types $Am'm'2'$ and $Amm'2'$ belong to the same magnetic *geometric crystal* class (i.e., have the same type of magnetic point group), but to two distinct magnetic *arithmetic crystal* classes. Lattice-equivalent magnetic space groups, also called translation-equivalent when the crystal is periodic, are denoted by taking the International symbol for $\mathcal{G}$, and adding a prime to those elements in the symbol that do not belong to $\mathcal{H}$ and must be followed by time inversion.

Enumeration of class-equivalent magnetic space-group types proceeds by considering all distinct pairs of lattices T_0 and T in a given crystal system, where T is a sublattice of index 2 in T_0 . Translations in the sublattice T , making up the Bravais lattice of $\mathcal{H}$, leave the periodic magnetic crystal invariant, while translations in T_0 that are not in T must be combined with time inversion to leave it invariant. Like a color-blind person, an X-ray diffraction experiment, which is insensitive to the magnetic ordering, will exhibit the reciprocal lattice L_0 of T_0 , while neutron diffraction will expose the additional Bragg peaks, contained in the reciprocal lattice L of T , encoding the magnetic order. Correspondingly, the lattice T_0 , and its reciprocal L_0 , are often called the colorless or colorblind lattices, as well as the paramagnetic or disordered lattices, while the sublattice T , and its reciprocal L , are often called the magnetic or ordered lattices.³ Note that while T is a sublattice of T_0 of index 2, their reciprocal lattices in Fourier space play opposite roles, whereby L_0 is a sublattice L of index 2.

Different settings and notations are used to describe class-equivalent magnetic space groups, depending on which of the two lattices—the magnetic or the paramagnetic—and which of the two spaces—real space or Fourier space—are considered as primary. In the Opechowski and Guccione (1965), or OG setting, the paramagnetic lattice of translations T_0 is considered primary, lending its symbol to the magnetic space group, while the magnetic lattice T is denoted as a subscript. In the OG setting the class-equivalent magnetic space group is considered a member of the magnetic superfamily of the space group $\mathcal{G}$. In the Belov, Neronova, and Smirnova (1964), or BNS setting, the magnetic lattice of translations T is considered primary, lending its symbol to the magnetic space group, while the paramagnetic lattice T_0 is indicated as a subscript. In the BNS setting the class-equivalent magnetic space group is considered a member of the magnetic superfamily of the space group $\mathcal{H}$. Finally, if one follows the Rokhsar, Wright, and Mermin (1988), or RWM formalism, in which the nonmagnetic space groups are viewed primarily in Fourier-space, and which generalizes most easily to aperiodic magnetic crystals (Lifshitz, 1997, Section V), the magnetic reciprocal lattice L is considered primary, lending its symbol to the magnetic space group, while the paramagnetic reciprocal lattice L_0 appears as a subscript. As in the BNS setting, the class-equivalent magnetic space group is considered a member of the magnetic superfamily of the space group H , but it is the subscript that denotes a sublattice of the main symbol as in the OG notation.

In the cubic system, for example, there are two lattice-sublattice pairs of index 2—the simple cubic lattice P has a face-centered sublattice F of index 2; and the body-centered cubic lattice I has a simple cubic sublattice P of index 2. The first pair is denoted P_F in the OG notation; F_S (S for simple) in the BNS notation; and I^*_P in the RWM notation, with the asterisk indicating that the lattice is specified in Fourier space. Recall that the reciprocal of an fcc lattice is a bcc lattice and vice versa. The second pair is denoted I_P in the OG notation; P_I in the BNS notation; and P_F^* in the RWM notation.

³The reference to order-disorder is motivated by transitions like the one that occurs in the β phase of brass (Madsen et al., 2016).

In the top part of Table 2 we enumerate all the cubic magnetic space group types with point group 432. Note that in addition to the different settings, there is a discrepancy in the different notations, which is due to the fact that when $\ell' \in G_M$, ordinary mirrors or rotations when unprimed may become glide planes or screw axes when primed, and vice versa. The only consistent way to avoid such confusion is to use only unprimed elements for the symbols of class-equivalent magnetic space-group types. This is the approach adopted by both the BNS and the RWM notations, but unfortunately not by the OG notation. Also note that there is no 1' at the end of the symbol, as it is clear from the existence of a subscript on the lattice symbol that the magnetic point group G_M contains ℓ' . Comparisons between the OG and the BNS notions, and discussions regarding the advantages and disadvantages of each approach, are still ongoing, with new notations being proposed to this day (Campbell et al., 2022; Grimmer, 2009, 2010; Litvin, 2016).

Tables of periodic magnetic space-group types in two and in three dimensions are given in the early work by Belov and Tarkhova (1964, Table 11), Belov et al. (1964, Table 10), Opechowski and Guccione (1965), Koptsik (1966), and Opechowski (1986, Tables 11.2 and 17.3); and more recently have also been made available online by Litvin (2013), Stokes and Campbell (2022) and by the Bilbao Crystallographic Server (2022), accompanied by the review of Perez-Mato et al. (2015). Let us only summarize some statistics. Starting from the 17 space-group types in 2 dimensions, also known as the 17 plane groups, one can form a total of 80 magnetic space-group types as follows: 17 colorless groups, 17 gray groups, and 46 black-and-white groups of which 20 are class-equivalent and 26 are lattice-equivalent. Starting from the 230 space-group types in 3 dimensions, one can form a total of 1651 magnetic space-group types as follows: 230 colorless groups, 230 gray groups, and 1191 black-and-white groups of which 517 are class-equivalent and 674 are lattice-equivalent. These numbers have no particular significance other than the fact that they may seem surprisingly large.

Magnetic symmetry of quasiperiodic crystals

Lattices and Bravais classes

Magnetically ordered quasiperiodic crystals, in general, possess no lattices of real space translations that leave them invariant, but they do have reciprocal lattices (or Fourier modules) L that can be inferred directly from their neutron diffraction diagrams. To be more concrete, consider a scalar spin-density field with a well defined Fourier transform

Each row lists the magnetic superfamily of one non-magnetic space groups G , listed in Column I by its International (Hermann-Mauguin) symbol and by its number from the International Tables in italics. Column II lists the trivial gray groups G' . Column III lists the lattice-equivalent space groups. Point group 432 has a single subgroup of index 2—the tetrahedral group 23—obtained by associating a prime with the twofold rotation axes (and consequently with the fourfold axes as well). This gives a single lattice-equivalent magnetic space-group for each nonmagnetic space group G . Point group 532 has no subgroup of index 2, and therefore no lattice-equivalent magnetic space-groups. Finally, there are two lattice-sublattice pairs in the cubic and the icosahedral systems. In both cases the simple or primitive lattice P has a face-centered sublattice F of index 2, and the body-centered lattice I has a simple or primitive sublattice P of index 2. Consequently, in the BNS setting, each non-magnetic fcc or fci space group gives rise to a single class-equivalent magnetic space group with an fcc or fci magnetic lattice and a primitive paramagnetic lattice, and each primitive space group gives rise to a single class-equivalent magnetic space group with a primitive magnetic lattice and a bcc or bci paramagnetic lattice. There are no class-equivalent magnetic space groups with a bcc or a bci magnetic lattice. These are listed in column IV in three different notations for the cubic groups and in the BNS and RWM notations for the icosahedral groups. For the RWM notation, recall that the reciprocal of a face-centered lattice F is a body-centered lattice in Fourier space, denoted by I^* , and vice versa. In total there are $8 + 8 + 8 + 6 = 30$ types of magnetic space groups with point group 432 and $6 + 6 + 4 = 16$ with point group 532.

$$S(\mathbf{r}) = \sum_{\mathbf{k} \in L} S(\mathbf{k}) e^{i\mathbf{k} \cdot \mathbf{r}}, \quad (2)$$

in which the set L contains at most a countable infinity of wave vectors. In fact, the *magnetic reciprocal lattice* L of a magnetic crystal can be defined as the set of all integral linear combinations of wave vectors $\mathbf{k}$, determined from its neutron diffraction diagram. Indeed, we expect to see a magnetic Bragg peak at every $\mathbf{k}$ in the closure of those that are experimentally observed, unless it is forbidden by symmetry, as explained in Section “*Extinctions in neutron diffraction of antiferromagnetic crystals*” below, or unless it is too weak to be detected experimentally.

The *rank* D of L is the smallest number of vectors needed to generate L by integral linear combinations. If D is finite the crystal is quasiperiodic. If, in particular, D is equal to the number d of spatial dimensions, and L extends in all d directions, the crystal is periodic. In this special case the magnetic lattice L is reciprocal to a lattice T of translations in real space that leave the magnetic crystal invariant, without applying time inversion. If $D > d$ the crystal is aperiodic, and the field $S(\mathbf{r})$ describes a magnetic quasicrystal. The reciprocal lattices L of magnetic crystals are classified into Bravais classes, just like those of non-magnetic crystals.

Phase functions and space-group types

We proceed by following the Rokhsar, Wright, and Mermin (1988, RWM) formalism and their notion of *indistinguishability*, used earlier to define the magnetic point group. The precise mathematical statement of this notion in the case of magnetic symmetry (Lifshitz, 1997, 1998) is the requirement that any symmetry operation of the magnetic crystal leave invariant all spatially averaged n th-order autocorrelation functions of its spin-density field,

$$C^{(n)}(\mathbf{r}_1, \dots, \mathbf{r}_n) = \lim_{V \rightarrow \infty} \frac{1}{V} \int_V d\mathbf{r} S(\mathbf{r}_1 - \mathbf{r}) \dots S(\mathbf{r}_n - \mathbf{r}). \quad (3)$$

One can prove (Lifshitz, 1997, in the Appendix) that two quasiperiodic spin-density fields $S(\mathbf{r})$ and $\hat{S}(\mathbf{r})$ are indistinguishable in this way, if their Fourier coefficients, defined in Eq. (2), are related by

$$\hat{S}(\mathbf{k}) = e^{2\pi i \chi(\mathbf{k})} S(\mathbf{k}) \quad (4)$$

where χ is a real-valued linear function (modulo integers) on L , called a *gauge function*. By this we mean that for every pair of wave vectors $\mathbf{k}_1$ and $\mathbf{k}_2$ in the magnetic lattice L ,

$$\chi(\mathbf{k}_1 + \mathbf{k}_2) \equiv \chi(\mathbf{k}_1) + \chi(\mathbf{k}_2), \quad (5)$$

where “ $\equiv$ ” means equal to within adding an integer. Thus, for each element g or g' in the magnetic point group G_M of the crystal, which by definition leaves the crystal indistinguishable, there exists a corresponding gauge function $\Phi_g(\mathbf{k})$ or $\Phi_{g'}(\mathbf{k})$, called a *phase function*, satisfying

$$S(g\mathbf{k}) = \begin{cases} e^{2\pi i \Phi_g(\mathbf{k})} S(\mathbf{k}) & g \in G_M, \\ -e^{2\pi i \Phi_{g'}(\mathbf{k})} S(\mathbf{k}) & g' \in G_M. \end{cases} \quad (6)$$

Since for any $g, h \in G$, $S([gh]\mathbf{k}) = S(g[h\mathbf{k}])$, the corresponding phase functions for elements in G_M , whether primed or not, must satisfy a *group compatibility condition*,

$$\Phi_{g^*h^\dagger}(\mathbf{k}) \equiv \Phi_{g^*}(h\mathbf{k}) + \Phi_{h^\dagger}(\mathbf{k}), \quad (7)$$

where the asterisk and the dagger denote optional primes. A *magnetic space group*, describing the symmetry of a magnetic crystal, whether periodic or aperiodic, is thus given by a magnetic (reciprocal) lattice L , a magnetic point group G_M , and a set of phase functions $\Phi_g(\mathbf{k})$ and $\Phi_{g'}(\mathbf{k})$, satisfying the group compatibility condition (7).

In particular, if the point group is gray, the phase function $\Phi_e(\mathbf{k})$ encodes all the information regarding the sublattice L_0 , earlier referred to as the paramagnetic or color-blind lattice. To see this, note that the relation $(e')^2 = e$ implies—through the group compatibility condition (7) and the fact that $\Phi_e(\mathbf{k}) \equiv 0$ —that $\Phi_{e'}(\mathbf{k}) \equiv 0$ or $1/2$. It then follows from the linearity of the phase function (5) that on exactly half of the wave vectors in L , $\Phi_{e'}(\mathbf{k}) \equiv 1/2$, and on the remaining half, $\Phi_{e'}(\mathbf{k}) \equiv 0$. The latter half form the sublattice L_0 , which is of index 2 in L .

Magnetic space groups are classified in this formalism into *magnetic space-group types* by organizing sets of phase functions satisfying the group compatibility condition (7) into equivalence classes. Two such sets Φ and $\hat{\Phi}$ are equivalent if: (I) they describe indistinguishable spin-density fields related as in (4) by a gauge function χ ; or (II) they correspond to alternative descriptions of the same crystal that differ by their choices of absolute length scales and spatial orientations. In case (I) Φ and $\hat{\Phi}$ are related by a *gauge transformation*,

$$\hat{\Phi}_{g^*}(\mathbf{k}) \equiv \Phi_{g^*}(\mathbf{k}) + \chi(g\mathbf{k} - \mathbf{k}), \quad (8)$$

where, again, the asterisk denotes an optional prime.

In the special case that the crystal is periodic ($D = d$) it is possible to replace each gauge function by a corresponding d -dimensional translation $\mathbf{t}$, satisfying $2\pi\chi(\mathbf{k}) = \mathbf{k} \cdot \mathbf{t}$, thereby reducing the requirement of indistinguishability to that of invariance to within a translation. Only then does the point group condition (6) become

$$S(g\mathbf{r}) = \begin{cases} S(\mathbf{r} - \mathbf{t}_g), & g \in G_M, \\ -S(\mathbf{r} - \mathbf{t}_{g'}), & g' \in G_M, \end{cases} \quad (9)$$

the gauge transformations (8) turn into the so-called Frobenius congruences (Senechal, 1990, page 69), which are related to simple shifts of the origin, and the whole description reduces to that given in Section “Magnetic symmetry of periodic crystals” for periodic crystals.

As an example, we enumerate in Table 2 the icosahedral magnetic space group types with point group 532, contrasting them with those of the cubic point group 432. Tables of magnetic space-group types on standard⁴ axial quasicrystals in two and three dimensions with arbitrary rotational symmetry, as well as magnetic space-group types in the icosahedral crystal system in three dimensions, are given by Lifshitz (1997, Section V).

Extinctions in neutron diffraction of antiferromagnetic crystals

We said earlier that every wave vector $\mathbf{k}$ in the lattice L of a magnetic crystal is a candidate for a diffraction peak unless symmetry forbids it. We are now in a position to understand exactly how this happens. Given a wave vector $\mathbf{k} \in L$ we examine all magnetic point-group operations g or g' for which $g\mathbf{k} = \mathbf{k}$. For such elements, the point-group condition (6) reduces to

$$S(\mathbf{k}) = \begin{cases} e^{2\pi i \Phi_g(\mathbf{k})} S(\mathbf{k}) & g \in G_M, \\ -e^{2\pi i \Phi_{g'}(\mathbf{k})} S(\mathbf{k}), & g' \in G_M, \end{cases} \quad (10)$$

requiring $S(\mathbf{k})$ to vanish unless $\Phi_g(\mathbf{k}) \equiv 0$ if $g \in G_M$, and $\Phi_{g'}(\mathbf{k}) \equiv 1/2$ if $g' \in G_M$. It should be noted that the phase values in Eq. (10), determining the extinction of $S(\mathbf{k})$, are independent of the choice of gauge (8), and are therefore uniquely determined by the magnetic space-group type of the crystal, regardless of the choice of gauge.

Particularly striking are the extinctions when the magnetic space group $\mathcal{G}$ is class-equivalent (type IV), implying that the magnetic point group G_M is gray (type 2), containing time inversion ϵ' . Equation (10) requires $S(\mathbf{k})$ to vanish on the whole paramagnetic sublattice L_0 , where $\Phi_{\epsilon'}(\mathbf{k}) \equiv 0$. Thus, in magnetic crystals with class-equivalent space groups (type IV), at least half of the diffraction peaks are missing. Fig. 4 shows the positions of the expected magnetic Bragg peaks corresponding to the tetragonal and octagonal magnetic structures shown in Figs. 2(a) and 3(a), illustrating this phenomenon. Further details on magnetic extinctions including tabulated results are given by Even-Dar Mandel and Lifshitz, 2004; Lifshitz (1998, 2000); Lifshitz and Even-Dar Mandel (2004).

Fig. 4 Extinctions of magnetic Bragg peaks in crystals with class-equivalent magnetic space groups (type IV). Both figures show the positions of expected magnetic Bragg peaks indexed by integers ranging from -4 to 4 . Filled circles indicate observed peaks and open circles indicate positions of extinct peaks. The origin and the D vectors used to generate the patterns are indicated by an additional large circle. (a) corresponds to the tetragonal crystal in Fig. 2(a) with magnetic space group p_4mmm and (b) corresponds to the octagonal crystal in Fig. 3(a) with magnetic space group p_8mm . Enc. of Cond. Mat. Phys. (Elsevier, 2005), p. 225.

⁴See Lifshitz (1997, footnote 8) for the meaning of “standard” in this context.

Conclusion: Generalizations of magnetic groups

There are two natural generalizations of magnetic groups, going beyond what is discussed here. One is to color groups (Lifshitz, 1997; Schwarzenberger, 1984; Senechal, 1988) with more than two distinct colors, and the other is to spin groups (Even-Dar Mandel and Lifshitz, 2004; Lifshitz, 1998, 2000; Lifshitz and Even-Dar Mandel, 2004; Litvin, 1973, 1977; Litvin and Opechowski, 1974) where the spins are viewed as classical axial vectors free to rotate continuously in any direction.

An n -color point group G_C is a subgroup of $O(d) \times S_n$, where S_n is the permutation group of n colors. Elements of the color point group are pairs (g, γ) where g is a d -dimensional (proper or improper) rotation and γ is a permutation of the n colors. As before, for (g, γ) to be in the color point group of a finite object it must leave it invariant, and for (g, γ) to be in the color point group of a crystal it must leave it indistinguishable, which in the special case of a periodic crystal reduces to invariance to within a translation. To each element $(g, \gamma) \in G_C$ corresponds a phase function $\Phi_{g,\gamma}(\mathbf{k})$, satisfying a generalized version of the group compatibility condition (7). The color point group contains an important subgroup of elements of the form (e, γ) containing all the color permutations that leave the crystal indistinguishable without requiring any rotation g .

A spin point group G_S is a subgroup of $O(d) \times SO(d_s) \times 1'$, where $SO(d_s)$ is the group of d_s -dimensional proper rotations operating on the spins, and $1'$ is the time inversion group as before. Note that the dimension of the spins need not be equal to the dimension of space (e.g., one may consider a planar arrangement of 3-dimensional spins). Also note that because the spins are axial vectors there is no loss of generality by restricting their rotations to being proper. Elements of the spin point group are pairs (g, γ) where g is a d -dimensional (proper or improper) rotation and γ is a spin-space rotation possibly followed by time inversion. Here as well, elements of the form (e, γ) play a central role in the theory, especially in determining the symmetry constraints imposed by the corresponding phase functions $\Phi_e^\gamma(\mathbf{k})$ on the patterns of magnetic Bragg peaks, observed in elastic neutron-diffraction experiments.

Acknowledgments

I would like to thank David Mermin for teaching me how to think about crystals and their symmetry, and Shahar Even-Dar Mandel for joining me in my investigation of the magnetic symmetry in quasicrystals. I also thank Alastair Rucklidge for his kind hospitality at the School of Mathematics at the University of Leeds, where this manuscript was prepared, as well as the Cheney Foundation for their support of my visit. My research in these matters is funded by the Israel Science Foundation, most recently through grant No. 1667/16.

Abstract

The description of crystal structures is given starting with some fundamental notions of crystal symmetry. The topics of lattices and space groups are briefly introduced and how these can be used with unit cell contents to describe the crystal structure. This leads to crystallographic databases where information on crystal structures is stored and can be searched. A brief discussion on refinement of diffraction information is given, together with the resulting geometric parameters.

Introduction

The bulk of our experimental knowledge of chemical structure, the arrangement of atoms in space, comes from the study of crystalline solids. This article intends to explain the nature of this chemical information, and how it may be extracted from the experimental results, given the form of the theoretical model used to describe the crystal structure.

This article first discusses some relevant elements of crystal symmetry and explains how the crystal structure is coded in a typical theoretical model. The information available from experimental techniques are used to establish crystal structures, especially X-ray diffraction and also diffraction of neutrons and electrons. A very large number of crystal structures have now been determined by these methods, and the resulting information is held in various crystallographic databases; these will therefore be described, focusing on the information they contain on individual determinations, which will typically include lattice parameters and space group, as well as the details of the unit cell contents as described by the refinement model used.

It is important to be able to evaluate the reliability of geometric descriptors derived from such a model, so refinement models and the published measures of the quality of the experimental structures determined are discussed. This is followed by a review of derived parameters, that is, those geometric descriptors of chemical interest.

Crystal symmetry

Ignoring defects, the crystal is a regular arrangement of identical building blocks, the unit cells, in three dimensions. The set of points equivalent to each other by the translation from one unit cell to another form a quasi-infinite three-dimensional geometric lattice, and, in order to describe a crystal structure, it is sufficient to define both this lattice and the structure or contents of an individual unit cell.

Crystal structures are characterized by their space group symmetry, that is, each structure falls into one of the 230 space group types detailed in International Tables for Crystallography. Each of these space groups falls into one of each of the broader categories of crystal system, Bravais lattice and crystal point group as shown below, that is, it will belong to a Bravais lattice type and a crystal point group within its crystal system.

[☆]*Change History:* October 2022. AM Glazer updated the whole article.

In general, a space group symmetry operation consists of a matrix R and a vector t , which generate from a position vector x an equivalent point x' as

$$x' = Rx + t$$

where R is an operation of the corresponding crystal point group. When R is the identity operation (100/010/001) the overall operation is a lattice translation, and t will be integral unless the lattice is centered in some way. Other point symmetry operations R may be combined with fractional translations t to form alternate space group operations (screw axes and glide planes). When the possible combinations of Bravais lattices and crystal point groups are considered, and include the cases where screw axes and glide planes replace the pure rotation axes or mirror planes of the point group, the 230 space group types result. Table 1 gives the crystal classes, along with, for each class, the lattice parameters required to define the unit cell, the possible centerings and the point groups, classified according to the presence of polarity and chirality. The equivalent points in the various centered lattices are shown in Table 2.

Table 1 Some properties of the crystal systems.

Crystal system	Restrictions on lattice parameters	Possible lattices	Point groups and their orders (in parentheses)			
			Nonpolar nonchiral	Polar nonchiral	Nonpolar chiral	Polar chiral
Cubic	$a(=b=c)$ ($\alpha = \beta = \gamma = 90^\circ$)	P,I,F	$m\bar{3}m$ (48) $\bar{4}3m$ (24), $m\bar{3}$ (24)		432(24), 23(12)	
Hexagonal	$a(=b) \neq c$ ($\alpha = \beta = 90^\circ$, $\gamma = 120^\circ$)	P	$6/mmm$ (24), $\bar{6}m2$ (12), $6/m$ (12), $\bar{6}$ (12)	$6mm$ (12)	622(12)	6(6)
Trigonal	$a(=b) \neq c$ ($\alpha = \beta = 90^\circ$, $\gamma = 120^\circ$)	P,R	$\bar{3}m$ (12), $\bar{3}$ (6)	3 m (6)	32(6)	3(3)
Tetragonal	$a(=b) \neq c$ ($\alpha = \beta = \gamma = 90^\circ$)	P,I	$4/mmm$ (16), $\bar{4}2m$ (16), $4/m$ (8), $\bar{4}$ (8)	4 mm (8)	422(8)	4(4)
Orthorhombic	$a \neq b \neq c$ ($\alpha = \beta = \gamma = 90^\circ$)	P,I,C,F	mmm (8)	$mm2$ (4)	222(4)	
Monoclinic	$a \neq b \neq c$ ($\beta \neq \alpha = \gamma = 90^\circ$)	P,C	$2/m$ (4)	m (2)		2(2)
Triclinic	$a \neq b \neq c$ $\alpha \neq \beta \neq \gamma$	P	$\bar{1}$ (2)			1(1)

Table 2 Lattice types and their equivalent points under translation.

Lattice type	No. of points	Equivalent points under translation are (x,y,z) +
P	1	(0,0,0)
C	2	(0, 0, 0) (1/2, 1/2, 0)

Unit cell contents

The unit cell of the crystal will normally contain a number of formula units of the constituent substance. Although the chemical formula may be easy to define in the case of elements and synthetic compounds, it may be problematic in the case of biological materials because of their complexity, and also for many minerals. Assuming that the formula mass, M , can be reasonably estimated, the number, z , of formula units per unit cell can be calculated from its dimensions, provided the density of the crystal, ρ , is known, since

$$z = \rho N_A U / M$$

where N_A is Avogadro's number and U the cell volume.

For macromolecular crystals such as proteins, this process is complicated by the large and uncertain amount of solvent generally present in the crystal and so contributing to M , and by the difficulties in obtaining accurate density measurements.

Once the number of each type of atom is known, the next stage is to describe how the mean atomic positions are distributed within the unit cell. In a simple case, this merely means describing the contents of that normally smaller volume which may be used to generate the complete unit cell through the space group operations. This volume, in mathematical terms the fundamental domain of the space group, is referred to as the asymmetric unit. The asymmetric unit is not normally uniquely defined; however, when rotation or inversion axes are present, they must lie at the borders of the asymmetric unit. (Centers of symmetry $\bar{1}$ and mirror planes $m = \bar{2}$, are special cases of inversion axes.)

The volume of the asymmetric unit may be calculated using data from Tables 1 and 2. The number of equivalent points generated by each crystal point group is given in parentheses against it in Table 1. The number of points equivalent by translation is given in Table 2 for each lattice type. Multiplying these two numbers together will give the factor by which the asymmetric unit is smaller than the unit cell. For example, the trigonal space group $R3c$ has a rho-mbohedral lattice (triply primitive = 3) and belongs to point group $3m$ (order 6). The unit cell is therefore 18 times larger than the asymmetric unit. This number is termed the multiplicity of the general position of the space group; the explanation of this follows.

We can define another number z' , the number of formula units in the asymmetric unit. For many structures $z' = 1$, and each of the atoms of the formula unit occupies a so-called general position within the asymmetric unit. In such a case, each atom's position is described by three arbitrary fractional coordinates (x_i, y_i, z_i). However, various exceptions exist. The most common is that $z' < 1$; this normally means that the positions of at least some of the atoms must coincide with one or more point symmetry elements (in addition to the identity), so that when the corresponding transformations are applied, their coordinates are unchanged. These atoms will lie on the boundaries of the asymmetric unit, and their coordinates will be restricted in some way. Such atoms are said to lie on special positions of the space group.

The various possible special or "Wyckoff" positions are listed, together with their multiplicities and local site symmetries, in International Tables for Crystallography. Where one or two coordinates are constricted, that special position type may be occupied by more than one type of atom (obviously with different free coordinates), whereas only one atom may occupy a special position comprising a set of points.

An example which illustrates many of these points, and where all the possible Wyckoff positions of the space group are used, is that of the isostructural crystals $M_3As_2O_8$ ($M = \text{Mg, Co}$). These have $z = 6$ in space group $I\bar{4}2d$. The Wyckoff positions for this space group are shown in Table 3; the general position with symbol e has multiplicity 16. This makes $z' = 3/8$ on the basis of the formula, and it immediately follows that elements M and As at least must lie on special positions or be disordered. The number of As atoms in the unit cell (12) cannot be satisfied by the multiplicity of one special position alone, and that of M (18) cannot even be satisfied by any combination of the special positions, which only have multiplicities of 8 or 4, unless some disorder is also present. The way in which these restrictions are resolved in the structure is also shown in Table 3, where all five Wyckoff position types are used. The As atoms are tetrahedrally coordinated (site symmetries 2 and $\bar{4}$ are subgroups of the tetrahedral group $\bar{4}3m$), and most of the M atoms are octahedrally coordinated (2 is a subgroup of $m\bar{3}m$), with one-ninth of the M atoms disordered among eight coordinate sites of symmetry $\bar{4}$.

Table 3 Distribution of the atoms over the Wyckoff positions of $I\bar{4}2d$ in the tetragonal $M_3As_2O_8$ phases.

Site multiplicity	Wyckoff symbol	Oriented site symmetry	Representative coordinates	Atoms	Occupancy	Contribution to cell contents		
						M	As	O
16	e	1	(x, y, z)	O(1)	1			16
				O(2)	1			16
				O(3)	1			16
8	d	$2\bullet$	$(x, 1/4, 1/8)$	M(1)	1	8		
				As(1)	1		8	
8	c	$2\bullet\bullet$	$(0, 0, z)$	M(2)	1	8		
4	b	$\bar{4}$	$(0, 0, 1/2)$	M(3)	0.5	2		
4	a	$\bar{4}$	$(0, 0, 0)$	As(2)	1		4	
					Totals	18	12	48

On the other hand, for molecular crystals, it is possible for the molecule (formula unit) to itself have some internal symmetry, and that $z' < 1$ indicates that some point symmetry elements of the molecule coincide with the site symmetry of a special position. Depending on the situation, this might not require any individual atoms to lie in special positions. Also, for molecular crystals, cases where $z' > 1$ are not uncommon, and rare cases exist where $z' = 1$ does not correspond to one molecule in a general position, but more than one in distinct special positions.

Crystallographic databases

The information on an individual structure will be held as a record on a crystallographic database. The main databases are CRYSTMET for metals and minerals, the Inorganic Crystal Structure Database (ICSD) for inorganic structures, the Cambridge Structural Database (CSD) for organic and organometallic structures, and the Protein Data Bank (PDB) for macromolecular structures. These are augmented by the Powder Diffraction File, the Surface Structure Database, and the Nucleic Acid Database for special purposes.

The information held in a database record (individual crystal structure) will include composition, lattice parameters, and space group, as well as basic details of the experiment and refinement. Typically, the databases as a whole are relational, or are otherwise structured to facilitate a wide range of possible searches. They are regularly updated with new crystal structures, but only after each submission has undergone an extensive validation procedure to ensure consistency and completeness, and to identify duplicate or related entries. Specialized software for search, retrieval, and visualization is made available to subscribers, along with regular updates to the databases themselves.

Applications of the databases fall into two main categories. First, there are searches for a single record or a limited group of records, as an aid in identification, structure description, property prediction, or possibly even structure determination through structure type. However, increasingly the databases are resources for “data mining,” the discovery of new information through statistical analysis of the entire database.

The refinement model

How to construct the standard refinement model of an inorganic or “small molecule” crystal structure is discussed here. The least-squares refinement, the predominant method, is assumed here. The mean positions of the nuclei are defined by their fractional coordinates—some of which may be constrained for atoms in special positions—and, for X-ray and electron diffraction, their surrounding electron density is assumed to be spherical, and is described by its Fourier transform, the scattering factor. The distribution of the instantaneous nuclear position about its mean is described by the Debye–Waller or temperature factor, either isotropic or anisotropic. The latter form requires six components for an atom in a general position or on a center of symmetry, but will be constrained for other types of special positions.

There will be an overall scale factor (sometimes more, depending on the details of the data collection), in addition to the parameters mentioned above. Atomic site occupancies may be varied to take account of disorder or substitution. Modern refinements may also vary the relative contributions from the various twin orientations which may be present, or the Flack parameter that describes the absolute structure (chirality) of a chiral crystal structure.

However, in evaluating the results of a crystal structure determination, it is important to distinguish those quantities which are determined in an unbiased way by the refinement, and those for which presumed chemical information was applied. In many cases, any attempt to refine all possible parameters is doomed to failure; but this does invalidate the results of a more cautious refinement. In practice, the parameters to be refined must be chosen in such a way as to maintain a well-behaved refinement process. The inclusion of parameters with little impact on the agreement between calculation and observation will produce near-singular least-squares matrices and hence excessive parameter shifts. For this reason chemical information is frequently included in the form of geometric constraints or, increasingly often these days, restraints. A typical constraint is to refine a molecule or group as a rigid body. In the case of restraints, the assumed dimensions of the molecule or group are treated as additional observations with appropriate estimated errors.

In X-ray diffraction, the weakly-scattering hydrogen atoms are normally constrained or restrained in some way, and their precise positions are usually unreliable.

Because of the limited quality of diffraction data from macromolecular crystals, it is not possible to refine such structures using the same sort of least-squares model as for small molecules, and so constraints or restraints are invariably necessary.

An alternative approach to crystal structure determination that is growing in popularity and reliability is that of Rietveld analysis of powder diffraction data.

Measures of quality

The quality of a structure refinement is generally reported as the conventional *R*-factor

$$R = \frac{\sum_i |\Delta F_i|}{\sum_i |F_i^o|}$$

This quantity is related to the actual measure normally minimized, the weighted R -factor based on $|F|^2$

$${}_2R_w = \frac{\sum_i w_i |\Delta F_i|^2}{\sum_i w_i |F_i^o|^2}$$

typically being about half. Another measure which may be reported is the goodness-of-fit S ,

$$S = \frac{\sum_i w_i |\Delta F_i|^2}{n - m}$$

which should be about unity if the standard errors of the observations are correctly estimated, and the model used is adequate to fit the observations (i.e., the errors in the model are negligible).

The conventional R -factor is a good rough guide to the quality of a structure determination, but has shortcomings in terms of comparing refinements on different crystal structures, because it does not take account of the distribution of structure factors in each particular data set. Data sets of high variance (hypercentric distributions, superlattices, and other pseudosymmetric structures), tend to refine to higher values of the R -factor, both because the higher proportion of very strong and very weak diffraction peaks that cannot be measured with the same precision as the others, and because such data sets are more sensitive to limitations in the model.

Typically, the databases allow some screening of the quality of the individual structure determinations in the search process. The CSD, for example, allows a cut-off maximum to be applied to the conventional R -factor, as well as the elimination of structures where disorder is present. It also allows the comparison of structures based on the quality of the derived geometric descriptors (see next section), in its case the average standard error in C—C bond lengths.

Derived geometric parameters

Much of the importance of crystal structure determination lies in the information available on bond lengths (i.e., internuclear distances), bond angles, and other geometric descriptors. These may be calculated by standard methods; either the fractional coordinates may be transformed to orthogonal distance coordinates,

$$\begin{aligned} X &= ax \\ Y &= ax \cos \gamma + by \sin \gamma \\ Z &= ax \cos \beta + by \sin \beta \cos \alpha^* + cz \sin \beta \sin \alpha^* \end{aligned}$$

where α^* is an angle of the reciprocal lattice, or the calculations may be made using the metric tensor for the crystal,

$$G = \begin{pmatrix} a \cdot a & a \cdot b & a \cdot c \\ b \cdot a & b \cdot b & b \cdot c \\ c \cdot a & c \cdot b & c \cdot c \end{pmatrix}$$

The first approach would be more appropriate for simple hand calculations, whereas the second is that used in molecular geometry programs.

It is also worthwhile to examine the validity of the anisotropic temperature factors determined by least-squares. These parameters may be visualized as ellipsoids using the ORTEP program (see Fig. 1). Very large or distorted thermal ellipsoids on individual atoms may indicate large amplitude internal motion or even short-range static disorder. The TLS (T—translation, L—libration, S—screw correlation) matrix formalism may be used to test whether individual atomic displacements within a molecule or group are consistent with rigid-body motion.

In addition to bond lengths and angles, metal and inorganic structures are frequently described in terms of coordination polyhedra. For organic and organometallic structures, additional descriptors are required to describe the molecular or group conformation; these include torsion angles and the deviation from planarity of a group of atoms.

The description of protein crystal structures is somewhat different. Precise bond lengths and angles are not experimentally accessible, but the various levels of organization are, these being:

1. primary structure, the sequence of amino acids present in each chain,
2. secondary structure, the local hydrogen-bonding patterns and chain torsion angles, which result in turn in the typical regular structures (helices and sheets),
3. tertiary structure, the three-dimensional relationships between the secondary structure elements, and
4. quaternary structure, the combination of protein chains to form the overall protein molecule.

Fig. 1 ORTEP drawing of an organic molecule in its crystal structure, showing hydrogen atoms as small spheres and nonhydrogen atoms as 50% probability ellipsoids. The elongation of the oxygen (labeled “O”) ellipsoids indicates large amplitude librations about the C—N bonds.

Abstract

The notion of periodicity in crystals is examined and how this can be varied in practice. In particular, the article discusses first of all the concept of superstructures, in which some sort of alternating motif occurs thus changing the repeat distance in a lattice. Crystals of this type are often incorrectly called in the literature superlattices: first of all they cannot be called lattices at all as they consist of atoms (a lattice must only consist of points). In any case such a superstructure is formed from a sublattice rather than a superlattice. In addition, some crystals do not have normal periodicity within a three-dimensional space, and are known as aperiodic crystals. Despite being aperiodic, they are still ordered. In mathematical terms they can be described with respect to a higher-dimension space and then projected back onto three dimensions. This generalizes our notion of what is meant by a crystal.

Lattices in two and three dimensions

A lattice is a periodic array of points generated by translation vectors (quasiperiodic lattices are discussed separately later). As an example, consider a two-dimensional rectangular lattice generated by the orthogonal vectors $\mathbf{a}_1$ and $\mathbf{a}_2$ (Fig. 1).

The lattice is assumed to be infinite in extent. Points on this lattice have position vectors

$$\mathbf{R} = n_1 \mathbf{a}_1 + n_2 \mathbf{a}_2 \quad (1)$$

where n_1 and n_2 are integers.

Lattices can be classified according to their symmetry properties. For example, the rectangular lattice in Fig. 1 has reflection lines which pass through the vertical and horizontal rows of points, and twofold rotation points coincident with the lattice points. Additional symmetry elements occur between the lattice points, as shown in Fig. 2.

According to the lattice condition, all points of the lattice must have the same environment; therefore, not all regular arrays of points are lattices. For example, in one dimension there is only one possible lattice type: an array of equally spaced points, as shown in Fig. 3.

If one classifies all two-dimensional lattices according to their symmetry elements, it is possible to show that there are only five distinct types, as shown in as Fig. 4.

The translation vectors define the edges of unit cells which are building blocks of the lattice. In two dimensions, the shape of the unit cell is specified by three lattice parameters: the magnitudes a and b of the translation vectors, and γ , the angle between the vectors (the magnitudes of the translation vectors are typically defined as $a = |\mathbf{a}_1|$, $b = |\mathbf{a}_2|$, and, in three dimensions, $c = |\mathbf{a}_3|$).

The choice of the unit cell is by no means unique. One could, for example, double the unit cells of Fig. 4 and generate the same lattice types. Unit cells containing only one lattice point are primitive; in this case, the positions of all lattice points can be written as integer sums of the translation vectors, as in Eq. (1). For the centered unit cell of Fig. 4c, the lattice points at the centers are given by half-integer sums of the translation vectors:

$$\mathbf{R}_{\text{center}} = (n_1 + 1/2)\mathbf{a}_1 + (n_2 + 1/2)\mathbf{a}_2 \quad (2)$$

Even primitive cells are not unique, since one could, for example, define an oblique primitive cell for the square lattice, as shown in Fig. 5.

In general, the conventional unit cell is chosen so as to be as small as possible, consistent with the underlying symmetry of the lattice. For example, the centered rectangular lattice (Fig. 4c) could be generated by an oblique primitive cell, but its symmetry elements are more obviously related to a rectangular unit cell (the symmetry elements of the centered rectangular lattice are identical to those of Fig. 2, with additional twofold rotation points along the cell diagonal). In other words, symmetry considerations can lead one to choose a conventional cell that is larger than a primitive cell.

The two-dimensional lattice types of Fig. 4 can be grouped within four systems based on the relative magnitudes of the translation vectors and the angle between them, as shown in Table 1.

[☆]Change History: September 2022. AM Glazer wrote section on 'Variations of periodicity: Superstructures and aperiodicity'.

Fig. 2 Symmetry elements of the rectangular lattice. The points of the lattice are indicated by open circles, reflection lines by solid lines, and twofold rotation points by lens-shaped symbols.

Fig. 3 Two periodic one-dimensional arrays of points. The lower example does not satisfy the lattice condition since some points have their nearest neighbor on the right, and some on the left.

Fig. 4 The five two-dimensional lattice types: (a) oblique, (b) rectangular, (c) centered rectangular, (d) square, and (e) hexagonal. Outlines of unit cells are shown by the dashed lines. Except for (c), all of the unit cells shown here are primitive.

Fig. 5 Several unit cells which can generate a square lattice type, including (a) a nonprimitive cell containing two lattice points, (b) a conventional primitive cell, and (c) an oblique primitive cell. In counting the number of lattice points assigned to a cell, points at corners, on sides, and within the cell are given weights of $1/4$, $1/2$, and 1 .

Table 1 The four two-dimensional systems.

System	Lengths	Angle ($^\circ$)
Oblique	$a \neq b$	$\gamma \neq 90$
Rectangular	$a \neq b$	$\gamma = 90$
Square	$a = b$	$\gamma = 90$
Hexagonal	$a = b$	$\gamma = 120$

Fig. 6 Upper drawings: two structures with identical rectangular lattice types but different bases. Lower: the same structures repeated with symmetry elements superimposed. (a) Space group $p2mm$, indicating a primitive lattice (p) with twofold rotation points (2), and two sets of mirror lines (mm), (b) space group pm , indicating a primitive lattice with a single set of mirror lines.

Note that the number of lattice types (five) is not equal to the number of systems (four), since there are two rectangular lattice types (primitive and centered).

A periodic physical system such as a naturally occurring crystal can be described as a lattice with repeating units known as a basis attached to each lattice point. The basis may consist of a single atom, a molecule, or a larger assembly. The space group that characterizes the entire structure results from the combined symmetries of the lattice and the basis. Since bases with different symmetries can be attached to a given lattice, one expects a greater number of space groups than lattices. In two dimensions, there are 4 systems, 5 lattice types, and 17 space group types. An example of two structures with the same lattice but different space groups is given in Fig. 7.

Different space groups also arise according to the arrangement of asymmetric molecules on similar lattices. For example, if every other molecule is flipped after displacement along a lattice translation vector, then a glide-reflection symmetry element is produced. (In the glide-symmetry operation, the structure is translated along the glide line and then reflected across the line.) Examples of two space groups with and without glide symmetry are shown in Fig. 7.

In three dimensions, lattices are generated by three translation vectors: a_1 , a_2 , and a_3 . It can be shown that there are 14 symmetrically distinct lattices which satisfy the lattice condition. These are the Bravais lattices; the conventional unit cells are shown in Fig. 8. The shapes of the unit cells are characterized by six lattice parameters: the magnitudes a , b , and c of the translation vectors, and the angles α , β , and γ , shown in Fig. 9.

The 14 Bravais lattices are distributed among seven crystal systems, with relative lattice parameters given in Table 2.

Fig. 7 Upper drawings: arrangements of identical molecules with and without glide-line symmetry. Unit cells are shown by the solid rectangles. Lower: the same structures with symmetry elements superimposed. (a) Space group $p1$: primitive lattice with no rotational, mirror, or glide symmetry. (b) Space group pg : primitive lattice with glide-line symmetry. (Note: the unit cell contains two molecules but only one lattice point, and is therefore primitive.)

Fig. 8 The 14 Bravais lattice types, with lattice translation vectors shown as solid arrows. (a) triclinic, (b) monoclinic, (c) base-centered monoclinic, (d) orthorhombic, (e) base-centered orthorhombic, (f) body-centered orthorhombic, (g) face-centered orthorhombic, (h) tetragonal, (i) body-centered tetragonal, (j) rhombohedral, (k) hexagonal, (l) cubic, (m) body-centered cubic, and (n) face-centered cubic.

Fig. 9 Three-dimensional lattice parameters. The lengths of the cell edges are the magnitudes of the translation vectors a , b , and c . The interaxial angles $a_1 \times a_3$, $a_2 \times a_3$, and $a_1 \times a_2$ are given by α , β , and γ .

Table 2 The seven three-dimensional crystal systems.

System	Lengths	Angles
Triclinic	$a \neq b \neq c$	$\alpha \neq \beta \neq \gamma$
Monoclinic	$a \neq b \neq c$	$\alpha = \beta = 90^\circ \neq \gamma$
Orthorhombic	$a \neq b \neq c$	$\alpha = \beta = \gamma = 90^\circ$
Tetragonal	$a = b \neq c$	$\alpha = \beta = \gamma = 90^\circ$
Trigonal	$a = b = c$	$\alpha = \beta = 90^\circ, \gamma = 120^\circ$
Hexagonal	$a = b \neq c$	$\alpha = \beta = 90^\circ, \gamma = 120^\circ$
Cubic	$a = b = c$	$\alpha = \beta = \gamma = 90^\circ$

Fig. 10 Examples of structures produced by adding a basis to a Bravais lattice. (a) h.c.p. cobalt. Pairs of atoms in the basis are connected by solid lines. The dashed lines show the edges of a hexagonal repeating structure with three times the volume of the conventional unit cell of Fig. 8k. (b) Cesium chloride. Open and filled circles represent oppositely-charged ions. The primitive cubic unit cell (also known as a simple cubic unit cell) is identical to that of Fig. 8l.

The combined symmetries of the 14 Bravais lattices and all possible bases lead to 230 space groups in three dimensions, first enumerated late in the nineteenth century and described explicitly in the International Tables for X-ray Crystallography. The classification of periodic structures as members of specific space groups is important in predicting properties, such as allowed reflections in X-ray diffraction, and allowed vibrational modes in optical spectroscopy.

A three-dimensional crystal can be “constructed” by placing a specific basis at each of the points of one of the 14 Bravais lattices. In the simplest case, the basis consists of a single atom and the full structure is simply that of the Bravais lattice. An example is face-centered cubic (f.c.c.) aluminum, which has the unit cell shown in Fig. 8n. As the complexity is increased, the basis can include more than one atom of the same element, as in hexagonal close-packed (h.c.p.) cobalt. In this structure, a basis consisting of two cobalt atoms is attached to the hexagonal lattice points, as shown in Fig. 10a. In the case of compounds, the basis contains two or more elements, as in cesium chloride, where the two-ion basis is attached to a primitive cubic lattice, as in Fig. 10b.

In all cases, it is the Bravais lattice (rather than the details of the basis) which determines the translational symmetry of the structure. That is, the crystal is invariant after a translation by a Bravais lattice vector, no matter what the basis is. This spatial periodicity results in the great utility of Fourier methods, as shown in the next section.

The reciprocal lattice, diffraction, and electronic band structure

A signal which is periodic in time can be conveniently described in terms of the strength of its harmonics. The signal can be defined completely in either the time or the frequency domain, using variables which have dimensions of time or inverse time. Similarly, a property such as the electron density of a spatially periodic structure can be described directly, in a space which has dimensions of length, or by a Fourier expansion in reciprocal lattice vectors, which have dimensions of inverse length. Many of the properties of a solid, such as its electronic band structure, are formulated most easily in reciprocal space (rather than direct space). Even from a purely structural standpoint, the reciprocal-space description is essential in the diffraction techniques which are used to solve crystal structures.

If one wishes to use the reciprocal lattice in order to describe physical properties, it is useful to define the reciprocal lattice as follows (in crystallography, the definition of the reciprocal lattice may differ slightly from that given here, for example, by the omission of the factors of 2π). Consider a solid with lattice translation vectors $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$. The reciprocal lattice vectors are defined by

$$\begin{aligned} \mathbf{b}_1 &= 2\pi \frac{\mathbf{a}_2 \times \mathbf{a}_3}{\mathbf{a}_1 \cdot \mathbf{a}_2 \times \mathbf{a}_3}, & \mathbf{b}_2 &= 2\pi \frac{\mathbf{a}_3 \times \mathbf{a}_1}{\mathbf{a}_1 \cdot \mathbf{a}_2 \times \mathbf{a}_3}, \\ \mathbf{b}_3 &= 2\pi \frac{\mathbf{a}_1 \times \mathbf{a}_2}{\mathbf{a}_1 \cdot \mathbf{a}_2 \times \mathbf{a}_3} \end{aligned} \quad (3)$$

The denominator of these expressions ($\mathbf{a}_1 \cdot \mathbf{a}_2 \times \mathbf{a}_3$) is the volume of the unit cell in direct space. The vectors $\mathbf{b}_1$, $\mathbf{b}_2$, and $\mathbf{b}_3$ are the translation vectors which define the reciprocal lattice, just as $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$ define the Bravais lattice in direct space. An arbitrary translation vector, which connects two points of the Bravais lattice, has the form

$$\mathbf{R} = n_1 \mathbf{a}_1 + n_2 \mathbf{a}_2 + n_3 \mathbf{a}_3 \quad (4)$$

where n_1 , n_2 , and n_3 are integers. Similarly, an arbitrary reciprocal lattice vector can be written as

$$\mathbf{G} = m_1 \mathbf{b}_1 + m_2 \mathbf{b}_2 + m_3 \mathbf{b}_3 \quad (5)$$

The form of the numerators in Eq. (3) leads to a compact expression for dot products between direct-space and reciprocal-space translation vectors. Note, for example, that $\mathbf{a}_2 \cdot \mathbf{b}_1 = \mathbf{a}_3 \cdot \mathbf{b}_1 = 0$ and $\mathbf{a}_1 \cdot \mathbf{b}_1 = 2\pi$. In general,

$$\mathbf{b}_i \cdot \mathbf{a}_j = 2\pi \delta_{ij} \quad (6)$$

This implies that any function of the form $e^{i\mathbf{G} \cdot \mathbf{r}}$ will have the translational symmetry of the Bravais lattice, because, for an arbitrary lattice translation vector $\mathbf{R}$,

$$\begin{aligned} e^{i\mathbf{G} \cdot (\mathbf{r} + \mathbf{R})} &= e^{i\mathbf{G} \cdot \mathbf{r}} e^{i\mathbf{G} \cdot \mathbf{R}} \\ &= e^{i\mathbf{G} \cdot \mathbf{r}} e^{i(m_1 \mathbf{b}_1 + m_2 \mathbf{b}_2 + m_3 \mathbf{b}_3) \cdot (n_1 \mathbf{a}_1 + n_2 \mathbf{a}_2 + n_3 \mathbf{a}_3)} \\ &= e^{i\mathbf{G} \cdot \mathbf{r}} e^{2\pi i(m_1 n_1 + m_2 n_2 + m_3 n_3)} = e^{i\mathbf{G} \cdot \mathbf{r}} \end{aligned} \quad (7)$$

For a Bravais lattice where the translation vectors $\mathbf{a}_1$, $\mathbf{a}_2$, and $\mathbf{a}_3$ are all perpendicular (these are the orthorhombic, tetragonal, and cubic cases), the corresponding reciprocal lattice can be immediately determined by inspection of Eq. (3). In this case, $\mathbf{b}_1 \parallel \mathbf{a}_1$ and $b_1 = 2\pi/a_1$. Similar relations hold for $\mathbf{b}_2$ and $\mathbf{b}_3$, that is, the reciprocal-space translation vectors are parallel to those in direct space, with magnitudes which are inversely proportional.

If the direct-space lattice vectors are not all perpendicular, then the reciprocal lattice vectors are not, in general, parallel to them, because, for example, $\mathbf{a}_2 \times \mathbf{a}_3$ may not be parallel to $\mathbf{a}_1$. Nonetheless, the reciprocal lattice vectors still have a straightforward interpretation in terms of lattice planes.

Lattice planes are labeled using Miller indices, which are assigned by taking the reciprocal of the intersection of the plane with each of the direct-space axes, as shown in Fig. 11.

In Fig. 11a, the first (100) plane which does not contain the origin, intersects the x-axis at a distance a from the origin. The plane is also parallel to the y and z axes; intersections with those axes are at infinity. Taking the reciprocal of these distances in lattice-parameter units, one obtains the Miller indices $(hkl) = (100)$ for these planes. Similarly, in Fig. 11b the intersections at (a, a, ∞) give $(hkl) = (110)$. In Fig. 11c, the intersections are $(\infty, a, a/2)$, giving Miller indices $(hkl) = (012)$.

If h , k , and l are integers, it can be shown that in any of the crystal systems a reciprocal lattice vector of the form

$$\mathbf{G}_{hkl} = h\mathbf{b}_1 + k\mathbf{b}_2 + l\mathbf{b}_3 \quad (8)$$

will be normal to the lattice planes with indices (hkl) . The magnitude will be inversely proportional to the spacing of the planes, specifically,

Fig. 11 Several examples of sets of planes in a cubic crystal, including (a) (1 0 0) planes, (b) (110) planes, and (c) (012) planes. Unit cells are shown with dashed lines and the sets of planes are in red. The corresponding reciprocal lattice vectors are normal to the planes and have magnitudes inversely proportional to the plane spacing.

$$G_{hkl} = \frac{2\pi}{d_{hkl}} \quad (9)$$

where d_{hkl} is the spacing of the (hkl) planes.

The relationship between G_{hkl} and the (hkl) planes leads to an important formulation of the diffraction condition in the reciprocal space of the crystal. Fig. 12 shows the geometry of the Bragg diffraction. The incident beam has wavelength λ and propagates along the direction given by the wave vector k_{inc} . The magnitude of the wave vector is defined by

$$k_{\text{inc}} = k_{\text{sc}} \equiv k = \frac{2\pi}{\lambda} \quad (10)$$

where the first equality indicates that the scattering is elastic. By setting the phase shift between waves scattered from neighboring planes equal to 2π , one obtains the Bragg condition for constructive interference (or diffraction) from the hkl planes:

$$\lambda = 2 d_{hkl} \sin \theta \quad (11)$$

By inspection of Fig. 12, and using Eqs. (10), (11), and (9), one obtains.

$$q = 2k \sin \theta = 2\pi \frac{2 \sin \theta}{\lambda} = \frac{2\pi}{d_{hkl}} = G_{hkl} \quad (12)$$

In other words, Bragg's law (Eq. (11)) can be reformulated as Eq. (12), which indicates that if constructive scattering from the (hkl) planes is to occur, then the magnitude of the scattering vector is equal to the magnitude of the corresponding reciprocal lattice vector. Since both q and G_{hkl} are normal to the scattering planes, Eq. (12) holds for the vector quantities as well:

$$q = G_{hkl} \quad (13)$$

Eq. (13) is the basis of the Ewald sphere representation of the diffraction condition, shown in Fig. 13. In an X-ray, electron, or neutron diffraction measurement, one maps out intensities associated with specific reciprocal lattice points. In essence, a diffraction measurement yields an image or a projection of the reciprocal lattice, and indirectly, information on the actual atomic ordering in the direct-space lattice.

The motion of an electron in a crystal is strongly affected by the periodic nature of the lattice. A nearly free valence electron interacts with relatively-fixed ion cores and experiences a potential, which can be written as an expansion in reciprocal-lattice vectors:

Fig. 12 Bragg scattering geometry. A beam with wave vector $\mathbf{k}_{\text{inc}}$ is incident with angle θ upon a set of atomic planes with spacing d_{hkl} . The scattered wave vector is $\mathbf{k}_{\text{sc}}$ and the scattering vector is $\mathbf{q}$. The small circles represent atoms or lattice points in direct space.

Fig. 13 The Ewald sphere construction of the diffraction condition $\mathbf{q} = \mathbf{G}_{hkl}$. This figure is drawn in reciprocal space; the small circles represent reciprocal lattice points, not atoms. The tip of the incident wave vector is placed at the origin, shown as a filled circle. The surface of the sphere gives the possible locations of the tip of an elastically scattered wave vector. When the diffraction condition is met, the scattered wave vector coincides with a reciprocal lattice point. In the example shown here, if the z -axis is assumed to be vertical, the Bragg condition for the $(0\ 0\ 4)$ reflection is met, that is, $\mathbf{q} = \mathbf{G}_{004}$.

$$U(\mathbf{r}) = \sum_j c_j e^{i\mathbf{G}_j \cdot \mathbf{r}} \quad (14)$$

As shown by Eq. (7), a potential-energy function written in this form will have the periodicity of the Bravais lattice:

$$U(\mathbf{r} + \mathbf{R}) = U(\mathbf{r}) \quad (15)$$

for any lattice vector $\mathbf{R}$. One might expect that the electron would be scattered erratically during its interaction with the ions; however, this is not the case. It can be shown that solutions of the Schrödinger equation in a periodic potential, such as that of Eq. (14), are Bloch functions:

$$\Psi(\mathbf{r}) = u_{\mathbf{k}}(\mathbf{r}) e^{i\mathbf{k} \cdot \mathbf{r}} \quad (16)$$

where $\hbar\mathbf{k}$ is the momentum of the electron, $e^{i\mathbf{k} \cdot \mathbf{r}}$ is a plane wave propagating in the direction of $\mathbf{k}$, and $u_{\mathbf{k}}(\mathbf{r})$ is a function which has the periodicity of the Bravais lattice, that is,

Fig. 14 Construction of Wigner–Seitz cells by drawing perpendicular bisectors of reciprocal lattice vectors. The first Brillouin zone is shown in red. Electron wave vectors and a scattering vector are shown in blue. The notation $\mathbf{G}_{100}$ indicates that the scattering vector runs from the origin to the first point to the left of the origin.

$$u_k(\mathbf{r} + \mathbf{R}) = u_k(\mathbf{r}) \quad (17)$$

Eq. (16) indicates that electrons can propagate freely through the crystal as plane waves modulated by the lattice. The energy $\varepsilon(\mathbf{k})$ of an electron in a particular momentum state will have a specific form that depends on the potential energy function $U(\mathbf{r})$. (For a free electron (when $U = 0$), $\varepsilon \propto k^2$.)

The effect of the periodic structure on the electron becomes very strong when the wave vector $\mathbf{k}$ takes on particular values. In order to see how this comes about, consider the region of reciprocal space near the origin. Then draw a series of lines which bisect the reciprocal-lattice vectors, starting with the shortest ones, as shown in Fig. 14. This construction divides the reciprocal space into Wigner-Seitz cells. In reciprocal space, the central cell which surrounds the origin is known as the first Brillouin zone (Wigner-Seitz cells can also be drawn in direct space. As an example, a primitive unit cell can always be constructed by generating such a cell about a Bravais lattice point).

Electrons with wave vectors within the Brillouin zone have propagating Bloch wave functions and can move through the crystal. However, if the wave vector $\mathbf{k}_{\text{inc}}$ terminates anywhere on the zone boundary, the electron can undergo Bragg diffraction to a new state $\mathbf{k}_{\text{sc}}$, since the difference between these wave vectors is equal to a reciprocal lattice vector. One can see that $\mathbf{k}_{\text{inc}}$ satisfies the condition for Bragg diffraction by comparing Fig. 14 to the Ewald sphere construction of Fig. 13.

When the Schrödinger equation is solved in a periodic potential (one of the simplest examples being the one-dimensional Kronig-Penney model), one finds that diffraction at the Brillouin zone boundary is accompanied by a discontinuity in the energy $\varepsilon(\mathbf{k})$, which is otherwise continuous within the zone. That is, a fundamental property of electrons in solids—the bandgap—follows directly from the periodicity of the Bravais lattice.

Variations of periodicity: Superstructures and aperiodicity

So far, we have assumed that lattices and crystal structures are infinite in extent and periodic. In this section, we shall look at some variations on this concept.

To begin with, we shall consider what is meant by a superlattice. Unfortunately, the condensed matter community consistently misuses this term. This is mainly because of a failure to distinguish between what is meant by a lattice and what is meant by a structure. As a reminder, a lattice is a periodic array of points (and therefore has no physical meaning but acts merely as a mathematical device for representing periodic symmetry). In contrast, a structure (or better an ideal crystal structure) is a periodic array of atoms or molecules.

Consider, for simplicity, some one-dimensional examples, as illustrated in Fig. 15. In (a), a series of points denotes a one-dimensional lattice with a unit cell repeat distance a . The translation vectors for this lattice are therefore given by

$$\mathbf{t}_n = n\mathbf{a}$$

Fig. 15 Examples of one-dimensional lattices and structures.

Fig. 16 Examples of superstructures in two dimensions, including (a) an ordered alloy, (b) an intercalated layered structure, and (c) a superstructure (heterostructure) prepared by the sequential deposition of two compounds. In all cases, the unit cell is marked by dashed lines.

In (b), a black horse is used to denote a molecule (i.e., consisting of either a single atom or many atoms) which is repeated in accordance with the translational symmetry of the lattice to form a one-dimensional crystal structure. Note that the unit cell of this structure is the same as for the lattice. In (c), every other lattice point has been removed so that now

$$t'_n = na' = 2na$$

The corresponding structure in our example is shown in (d), where every other molecule has been replaced, in this case, by a white horse. Now, the lattice in (c) contains half the number of lattice points (a), so this is a **SUBLATTICE**, not a superlattice! On the other hand, the structure in (d) has a doubled unit cell and so it consists of supercells. Therefore, it can be described as a **SUPERSTRUCTURE**! We see therefore the source of the confusion in the literature. The first mistake is to refer to the structure (d) as a superlattice, when in fact, it is not a lattice but a crystal structure. The second error is in using the term superlattice, when in fact, the corresponding lattice is a sublattice.

In diffraction, the structure in (a) gives rise to reflections periodically spaced in proportion to $1/a$, whereas for (d), extra reflections appear halfway between the main reflections (generally weaker in intensity than the main reflections). Such extra peaks are often called in the literature superlattice peaks, but this again causes confusion between the fundamental notions of lattice and structure. Better terminology is probably to call the extra peaks superstructure peaks, as they arise from the occurrence of a superstructure.

These concepts can be generalized to higher dimensions (Fig. 16).

In (a), two types of atoms are shown in an alternating array in all directions, typical of what is observed in an ordered metal alloy, for example, in β -brass (CuZn) at low temperature. In (b), layers of a foreign substance are intercalated between atomic layers to

form a layered structure, typically found in clay minerals or when graphite has foreign atoms between the carbon layers. As with the ordered alloy, the enlargement of the unit cell, relative to that of the pure host, leads to additional superstructure reflections. As in the alloys, the increase in cell size often occurs in more than one direction, and so the array of new reflections can be one-, two-, or three-dimensional.

It is also possible to produce artificial, so-called heterostructures by sequential deposition of thin layers of dissimilar materials onto a substrate (c). Such structures are well known in semiconductor quantum-well systems or in magnetic multilayers. Here, the unit cell is enlarged only in one direction, and so the corresponding diffraction pattern consists of rows of new features normal to the layers.

Layers of atoms can often form on the surfaces of clean metals and semiconductors, a process often known as surface reconstruction. Although the reconstruction occurs on a bulk solid, its structure and reciprocal lattice can, to a certain extent, be considered as that from a very thin isolated layer whose symmetry is that of a subperiodic group known as a layer group. In this case, the Bragg reflections become elongated to form rods of scattering perpendicular to the surface.

So far, crystal structures have been described as being periodic and conforming to seven crystal systems and fourteen Bravais lattice types. In 1984, a rapidly-cooled metallic Al_4Mn alloy was observed by the Israeli-born materials scientist Daniel Shechtman to exhibit 10-fold symmetry in its electron diffraction pattern. This seemed to show that these materials, in some way, violated the rule that crystals could not show 5 or 10-fold symmetry. At first, Shechtman was disbelieved, and he initially found it difficult to be taken seriously. He was eventually proved correct and was awarded the Nobel Prize in 2011 for his discovery. Such materials have become known as quasiperiodic crystals or quasicrystals, and they clearly could not be explained by conventional crystal-symmetry arguments. Other examples appeared after this initial discovery, including naturally formed icosahedrite, a mineral with the composition $\text{Al}_{63}\text{Cu}_{24}\text{Fe}_{13}$. It is possible even to grow crystals with observable faces exhibiting fivefold symmetries.

Two types of quasicrystals are known. The first type, polygonal (dihedral) quasicrystals, have an axis of 8, 10, or 12-fold local symmetry (octagonal, decagonal, or dodecagonal quasicrystals, respectively). They are periodic along this axis and quasiperiodic in planes perpendicular to it. The second type, icosahedral quasicrystals, is aperiodic in all directions. The term aperiodic applies to those cases where long-range periodicity is not a feature of the solid, such as in amorphous materials like glass. The term aperiodic crystal is used to describe crystals where translational periodicity does not apply. Nonetheless, the atoms or molecules are arranged in some sort of order generated by different rules from the usual periodic rules.

One way to envisage quasi-periodicity is in considering the tiling of a floor without leaving gaps. In the conventional approach, a set of identical regular tiles of two-, three-, four-, and sixfold symmetry ends up with periodicity, but this is not possible with tiles having five or sevenfold symmetry. However, if one is prepared to use differently-shaped tiles, one can obtain many arrangements with local five or sevenfold symmetries. Perhaps the most famous example is that due to Roger Penrose, where two different shapes are used. In this case, with appropriate rules for stacking, fat and thin rhomb shapes can be placed together to fill two-dimensional space. Such an arrangement never repeats although it does show local orientational symmetry of a fivefold kind. Interestingly, if one superimposes a series of lines (Fig. 17), due to Robert Ammann (1946–94), as shown, the sets of lines together show evidence of fivefold symmetries! Furthermore, the lines are spaced by long (L) and short (S) distances in the sequence L S L L . . . This sequence has an interesting property. If you replace every L by LS and every S by L, you find the series L S L L S L S . . . This is simply a copy of the original sequence. This type of sequence is found in many places in nature and is known as a Fibonacci sequence. It is interesting

Fig. 17 Penrose tiling and lines due to Ammann.

Fig. 18 The strip/projection method from two dimensions to one dimension.

to note that the ratio L/S is the 'golden mean' $\tau = (1 + \sqrt{5})/2 = 1.61803 \dots$. This arrangement is not random, nor is it periodic. It is not obvious what the overall symmetry is of an aperiodic arrangement in direct space, such as in the Penrose tiling example, where the fivefold symmetries are local. However, in reciprocal space, as seen through diffraction, the symmetry is revealed.

As a consequence of Shechtman's discovery, in 1992, the International Union of Crystallography revised the definition of a crystal in terms of reciprocal space, and more recently this has been revised yet again to include direct space. The definition is now as follows:

Direct-space definition: A solid is a crystal if its atoms, ions and/or molecules form, on average, a long-range ordered arrangement. In most crystals the arrangement is a periodic array that is governed by the rules of translational symmetry. In aperiodic crystals (incommensurate and quasicrystals) the arrangement is not periodic in three dimensions but is nevertheless still fully ordered, where the ordering follows particular mathematical rules.

Reciprocal-space definition: A solid is a crystal if it has essentially a sharp diffraction pattern. The word essentially means that most of the intensity of the diffraction is concentrated in relatively sharp Bragg peaks, besides the always present diffuse scattering. In all known cases, the positions of the diffraction peaks can be expressed by

$$\mathbf{H} = \sum h_i \mathbf{a}_i^* \quad (n \geq 3)$$

Here $\mathbf{a}_i^*$ and h_i are the basis vectors of the reciprocal lattice and integer coefficients, respectively, and the number n is the minimum for which the positions of the peaks can be described with integer coefficient h_i . The conventional crystals are a special class, though very large, for which $n = 3$ (The adjective 'known' reflects the fact that it is possible to envisage mathematically-based models that lie outside these definitions. See e.g., Grimm (2015)).

One important consequence of this definition is that an aperiodic crystal becomes periodic in a higher dimensionality n .

This can be illustrated by reference to Fig. 18. Starting with a simple square regular lattice, a slice is taken from O to R. Lattice points within this strip are then projected onto the line OR. This one-dimensional array of points, marked in red, forms a quasilattice, in which the spacings between them are either long (L) or short (S). With a suitable choice of the angle α the arrangement of long and short spaces can form a Fibonacci series. We see, therefore, that starting with a 1-d quasilattice, one can find a perfect lattice in a higher-dimensional space. This idea can be generalized to quasi-arrays in 2 and 3 dimensions.

Abstract

Determination of crystal structures from diffraction requires first the solution of the crystallographic phase problem. Solving the phase problem is equivalent to the determination of atomic positions in the crystal structure and, as such, it is an essential part of the structure determination. Numerous methods have been developed for this purpose. They can be classified into several classes: ab initio methods include Patterson method, direct methods and dual space iterative algorithms. These methods do not require much more information than the diffraction data. Direct space methods like simulated annealing and genetic algorithms are used mostly for structure solution from powder diffraction data. They can handle lower data quality, but they require additional information, typically molecular connectivity.

Key points

- Crystal structure determination requires the solution of the phase problem
- Phase problem means unknown phases need to be assigned to Fourier coefficients of the scattering density, of which only amplitudes are known

[☆]*Change History:* March 2023. L. Palatinus updated all changes, R. Spagna approved the changes. The chapter was thoroughly updated and extended. Only specific sections from the previous versions were reused. These include Statistical analysis, Normalized structure factors and Probability distribution, which form sections Structure factor normalization and Reflection statistics in the new version. Patterson function, Direct methods (shortened). Other sections are newly written.

*Retired.

- Two main classes of methods for the solution of the phase problem exist in the field of small-molecule and inorganic crystallography: ab initio methods, direct space methods
- Ab initio methods include the Patterson method, direct methods, and dual space iterative algorithms
- Direct-space methods involve simulated annealing and genetic algorithms.

Introduction

Diffraction of X-rays by a crystal can be described in terms of a complex quantity called the structure factor, which is the Fourier transform of the electron density in the unit cell of the crystal (Mueller and Weiss, 2023). The diffraction occurs in discrete directions, which are determined by the orientation of the crystal with respect to the incident beam, and the *reciprocal lattice*, which is a dual lattice to the lattice of the crystal. Each diffracted beam can thus be assigned the three indices of the reciprocal lattice node it belongs to, typically denoted as $\mathbf{h} = (h, k, l)$. The amplitude and phase of the wave diffracted into the node $\mathbf{h}$ is the structure factor, and it can be computed as

$$F_{\mathbf{h}} = |F_{\mathbf{h}}| \exp(i\phi_{\mathbf{h}}) = \sum_{j=1}^N f_j(\mathbf{h}) \cdot DWF \cdot \exp(2\pi i \mathbf{h} \cdot \mathbf{x}_j)$$

The summation runs over all atoms in the unit cell of the crystal, f_j is the scattering power of the atom j in the direction given by $\mathbf{h}$, $\mathbf{x}_j$ is the vector of fractional atomic coordinates of atom j and DWF is the Debye-Waller factor, which accounts for the effects of the thermal motion and other random displacements of the atoms on their scattering power, and usually takes the form $DWF = \exp(-Bh^2/4)$ with B being the displacement parameter characterizing the extent of the displacement. If f_j is considered a general function of $\mathbf{h}$, then the above expression can be considered exact. In practice, however, the structure is almost always considered to be composed of independent, non-interacting atoms, whose electron density is not deformed by interatomic interactions. In such case the atoms are spherical and f_j is a function of only the length of $\mathbf{h}$, it can be tabulated for each atomic type, and the structure factor can then be easily, and to a very good accuracy, calculated only from the knowledge of atomic types and their coordinates in the unit cell.

Once the structure factors are known, the electron density, $\rho(\mathbf{x})$ can be calculated:

$$\rho(\mathbf{x}) = V^{-1} \sum_{\mathbf{h}=-\infty}^{\infty} F_{\mathbf{h}} \exp(-2\pi i \mathbf{h} \cdot \mathbf{x}) = V^{-1} \sum_{\mathbf{h}=-\infty}^{\infty} |F_{\mathbf{h}}| \exp(i\phi_{\mathbf{h}}) \exp(-2\pi i \mathbf{h} \cdot \mathbf{x})$$

To obtain the exact electron density, a complete (infinite) set of structure factors is needed. However, a finite set of the most important structure factors (those with low $|\mathbf{h}|$) is needed in practice to obtain a good representation of $\rho(\mathbf{x})$.

In a diffraction experiment, the intensities of diffracted beams are detected on a detector. Under suitable approximations (kinematical diffraction, or the first Born approximation), the intensity is proportional to the amplitude-squared of the structure factor:

$$I \propto |F_{\mathbf{h}}|^2$$

Thus, the phase $\phi_{\mathbf{h}}$ of the structure factor is lost in the experiment and is not available. As a consequence, it is not possible to calculate the electron density directly from the quantities obtained in a diffraction experiment. The phases need to be recovered by other means. This problem is known as the *crystallographic phase problem*, and a lot of effort was dedicated to solving this problem. This text reviews the most important methods used to solve the crystallographic phase problem in several scenarios.

Types of input data

Several approaches to the solutions to the phase problem have been devised. Their use is to a large extent governed by the type of diffraction data available. The two key types of data with very different properties and thus information contents are single-crystal and powder diffraction data. As the name indicates, single-crystal data are obtained by performing the experiment on a single, monocrystalline piece of material. In such a case, individual intensities of all structure factors up to the maximum obtainable resolution (i.e., the maximum length of the vector $\mathbf{h}$) can be determined. If the resolution is sufficient, ab initio methods can usually be used. The limit for “sufficient” resolution is not strict, but generally the value for $d_{\min} = 1/|\mathbf{h}| = 1.2 \text{ \AA}$ is considered border-case, especially for organic compounds. Most inorganic and small-molecule crystal structures, and even some macromolecular crystals provide data with sufficient resolution and are thus suitable for the application of ab initio methods (Fig. 1a). However, most crystals of macromolecules do not allow collecting measurable intensities up to sufficient resolution. In this case, special approaches are needed.

The second major type of diffraction data are powder diffraction data, which are obtained by diffraction on a large assembly of very small crystals. The diffraction pattern is then composed of a very large number of randomly oriented diffraction patterns.

Fig. 1 (a) a diffraction pattern collected on a single crystal. Rings show the resolution in $d = 1/|h|$ (b) a diffraction pattern collected on a powder sample.

Each reflection is thus distributed over a ring on the detector, and the diffraction can be represented as a one-dimensional pattern of intensity vs. diffraction angle (Fig. 1b). Due to the compression of the information from three dimensions to one, these data suffer from reflection overlap, especially at higher diffraction angles. Therefore, the individual reflection intensities cannot be extracted. Although *ab initio* methods can also be sometimes applied, the most common approach to the structure solution from powder diffraction data are the direct space methods.

Structure factor normalization

Before discussing individual approaches to the solution of the phase problem, it is useful to discuss the treatment of the intensities that makes them more suitable for the application of the phasing methods. The intensities are proportional to the structure-factor amplitude squared, but the proportionality constant is not known. Moreover, the Debye-Waller factor, which characterizes the effect of thermal vibrations on the intensities, is also not known.

Wilson (1942) proposed a simple method to put the observed amplitudes $|F_h|_{obs}$ on an absolute scale, based on statistical analysis. He showed that the average of the squared structure amplitudes should be:

$$\langle |F_h|^2 \rangle = \sum_{j=1}^N f_j^2 = \sigma^2.$$

assuming that thermal motion is isotropic and equal for all the atoms:

$$\langle |F_h|^2 \rangle_{obs} = K \langle |F_h|^2 \rangle \exp\left(-\frac{Bh^2}{4}\right)$$

where K is the scale factor. A plot of the logarithm of the function vs. h^2 at some average value of h^2 would derive the values of K and B . The intensities can then be rescaled to bring them on absolute scale and remove approximately the effect of atomic displacement.

Such corrected intensities are still dependent on the atomic type, through the atomic scattering factors f_j . However, once the intensities have been corrected for thermal motion and placed on an absolute scale, it is simple to remove this dependence, too, and obtain the normalized structure magnitudes $|E_h|$ from

$$|E_h|^2 = \frac{|F_h|^2}{\varepsilon \sigma^2}$$

where ε are numbers that vary with space group and type of reflections. These quantities are independent of the scattering angle and correspond to idealized point atom structures:

$$E_h = \sum_{j=1}^N \exp(2\pi i \mathbf{h} \cdot \mathbf{x}_j)$$

These quantities depend solely on the positions of the atoms in the unit cell. Owing to this peculiarity, the values E_h play a key role in *ab initio* phasing methods, especially direct methods.

Reflection statistics

Hughes (1949) empirically, and Wilson (1949) by taking the analogy with the random-walk problem found that the diffracted intensities of a centrosymmetric crystal obey a Gaussian distribution. Expressed in terms of $|E|$, the centric distribution is (Fig. 2a):

$$P_1(|E|) = \sqrt{\frac{2}{\pi}} \exp\left(-\frac{|E|^2}{2}\right)$$

In further studies, the acentric distribution, i.e., the distribution of intensities of a non-centrosymmetric crystal, was obtained (Fig. 2b):

$$P_1(|E|) = 2|E| \exp(-|E|^2)$$

These distributions are independent of the structure complexity. Theoretical values of the moments of higher order and the cumulative probability functions of $|E|$ can be calculated from the distributions. These values can be compared with the corresponding experimental values to argue about the presence or absence of a center of symmetry, which is otherwise very difficult or impossible to determine from diffraction data alone. The centric and acentric distribution were, however, derived under the assumption of a random distribution of essentially equal atoms in the unit cell of the crystal and as such are just an approximation. Distributions derived from experimental data may differ from the theoretical ones due to the special features in the structure like a combination of heavy and light atoms, atoms in special high-symmetry positions, pseudosymmetry or twinning.

Classification of phasing methods

It was made clear in the previous section that various types of data require various approaches to phasing. The most general methods, from the point of view of external information needed for phasing, are so called *ab initio* phasing methods. These methods require solely the diffraction data as an input. No other information about the crystal structure, sometimes not even the chemical composition, is needed. The three main methods in this family are the Patterson method, direct methods and dual space iterative algorithms.

If individual structure factor amplitudes are not known, like in powder diffraction, or if they are not sufficiently accurate for application of direct methods, then direct space methods can be used. These methods, most of them genetic algorithms or simulated annealing, also in principle do not require much more than the diffraction data and chemical composition. However, the complexity (and thus computation time) of the solution grows exponentially with the number of free parameters, and it is therefore necessary to provide additional information, typically molecular connectivity, to solve all but the simplest problems.

When diffraction data are collected to low resolution only, and the number of atoms in the structure is large (sometimes many thousands), typically from crystals of proteins, then *ab initio* methods fail, and the problem is too complex for direct space methods. Then, special methods developed for macromolecules are needed. These are either so called molecular replacement, where the initial structure model is obtained by locating a known fragment from a similar molecule, or experimental phasing methods, which exploit the differences in diffraction from very similar, yet slightly different structures, or the differences between diffraction at various wavelengths of the radiation.

Fig. 2 The centric and acentric distributions of normalized amplitudes.

Ab initio phasing methods

Patterson function

Patterson (1934) introduced a function which is the convolution of electron density $\rho(\mathbf{x})$ with itself:

$$P(\mathbf{u}) = \int_V \rho(\mathbf{x}) \cdot \rho(\mathbf{u} + \mathbf{x}) d\mathbf{x}$$

The Patterson function can be directly calculated from the set of squared but not phased reflection amplitudes $|F_h|^2$

$$P(\mathbf{u}) = \frac{1}{V} \sum_h |F_h|^2 \cos 2\pi \mathbf{h} \cdot \mathbf{u}$$

where V is the volume of the unit cell. The map computed gives a vectorial representation of the scattering objects (Fig. 3). This depends upon the fact that while F_h is related to the distribution of the atoms in the crystal, $|F_h|^2$ depends on the distribution of interatomic distances. In fact,

$$|F_h|^2 = F_h \cdot F_h^* = \sum_{j=1}^N f_j^2 + \sum_{i \neq j=1}^N f_i f_j \cos [2\pi \mathbf{h} \cdot (\mathbf{x}_i - \mathbf{x}_j)]$$

depends on the distances $(\mathbf{x}_i - \mathbf{x}_j)$ between the i and j atoms.

N atoms in the structure thus generate $N(N-1)$ peaks in the Patterson function. This higher density of peaks with respect to the electron density makes the Patterson map difficult to interpret even with a moderate number of atoms.

Because the density in the Patterson map goes as squares of the numbers of electrons of the scattering atoms, Patterson maps of crystals that contain heavy atoms are dominated by the vectors between them.

Harker noticed that the symmetry of a crystal might provide particular vectors that would lead to a direct determination of the coordinates of individual atoms. For example, if the crystal's symmetry included an inversion center, there would be equivalent atoms at positions (x, y, z) and $(-x, -y, -z)$. The vector between these atoms would be found at $(2x, 2y, 2z)$ in the Patterson map, indicating the original atomic positions. This procedure greatly simplifies the interpretation of the Patterson map and allows one to obtain a good initial model; in fact, the structure factors F_h^c calculated with the heaviest atoms, f_1 and f_2 , represent the predominant contribution to the structure factors F_h (Fig. 4).

The phase φ_h^c is a good approximation of the true phase of F_h and an electron density map using as coefficients the observed structure factors and the calculated phases φ_h^c can be computed. The remaining atoms will be found following the so-called method of Fourier synthesis recycling, which is described later. This application of the Patterson function is called the heavy atom method.

Fig. 3 (a) a planar structure of 5 atoms. (b) the corresponding interatomic vectors. (c) Patterson map with all interatomic vectors translated to the origin.

Fig. 4 Visualization of the heavy atom method in an Argand diagram. f_1 and f_2 are the contributions of the heavy atoms, forming partial structure factor F_h^c , which is a good approximation to the total structure factor F_h , because the remaining contributions are small.

Direct methods

Direct methods are those methods that exploit relationships among the intensities to determine the crystal structure directly.

In general, the phase, ϕ , and the amplitude, $|F|$, of a wave are independent quantities and only the amplitudes are obtainable from experiment. However, in diffraction from crystal structures these two sets of quantities are not independent and they can be related thanks to two properties of the electron density: (1) it is positive everywhere and (2) it is composed of discrete atoms.

Experimentally, a large number, M , of amplitudes can be measured and then a system of simultaneous equations formed by the definition of crystal structure factors can be written. The unknown quantities are the phases ϕ_h and the atomic positions $\mathbf{x}_j$, the known quantities are the $|F_h|$ obtained from the measured intensities. Since the equation involves complex quantities, two equations, one for real and one for the imaginary part, can be considered. Therefore, there are $2M$ equations to determine $(M + 3N)$ unknown quantities and since the number of equations exceeds, by far, the number of unknowns, the problem to determine the phases is in principle over-determined.

Sayre (1952) derived a basic relationship between structure factors. Considering the structure composed of fully resolved and identical atoms, the two functions $\rho(\mathbf{x})$ and $\rho^2(\mathbf{x})$ must be very similar and show maxima at the same position.

Using this similarity, the following relationship, called Sayre's equation, can be derived:

$$F_h = \frac{\theta_h}{V} \sum_{\mathbf{k}} F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}}$$

Here V is the volume of the unit cell and $\theta_h = \frac{f_h}{s_h}$ is the ratio between the scattering factors of $\rho(\mathbf{x})$ and $\rho^2(\mathbf{x})$. Multiplying both sides by F_h :

$$|F_h|^2 = \frac{\theta_h}{V} \sum_{\mathbf{k}} |F_{\mathbf{k}} F_{\mathbf{h}-\mathbf{k}}| \exp[i(\phi_{-\mathbf{h}} + \phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}})]$$

For large values of $|F_h|$, the left-hand side will be large, real and positive. It is therefore likely that the largest terms in the sum on the right-hand side will also be real and positive. It follows that, if $F_{\mathbf{k}}$ and $F_{\mathbf{h}-\mathbf{k}}$ also have large moduli, the phases are linked by the relationship:

$$\Phi_{hk} = \phi_{-\mathbf{h}} + \phi_{\mathbf{k}} + \phi_{\mathbf{h}-\mathbf{k}} \cong 0 \pmod{2\pi}$$

This probabilistic condition for three reflections with large structure factors has proved to be the most important original approach for the practical use of direct methods.

Structure Invariants

A structure invariant (s.i.) is a quantity which remains unchanged when the origin is arbitrary shifted. The intensities are, of course the simplest example of structure invariants, while the phases are, in general, dependent on the choice of the origin. Under certain conditions, phase relationships between structure factors are independent of this choice and are thus also s.i. The most general structure invariant relationship is represented by:

$$F_{h_1} F_{h_2} \cdots F_{h_m} = |F_{h_1} F_{h_2} \cdots F_{h_m}| \exp[i(\phi_{h_1} + \phi_{h_2} + \cdots + \phi_{h_m})]$$

where

$$\mathbf{h}_1 + \mathbf{h}_2 + \dots + \mathbf{h}_m = 0$$

Since the moduli of the structure factors are invariants themselves, the angular part:

$$\Phi_m = \phi_{h_1} + \phi_{h_2} + \dots + \phi_{h_m}$$

is also a s.i. The most important of these general relationships is the case of three structure factors. The corresponding invariant is called the triplet invariant.

Probability methods

Probability methods were introduced by Hauptman and Karle (1953) and led to the joint probability distributions of a set of normalized structure factors. The distribution associated with triplet invariants for a non-centrosymmetric structure is given by:

$$P(\Phi_{hk}) = \frac{1}{L} \exp(G_{hk} \cos \Phi_{hk})$$

And

$$G_{hk} = \frac{2}{\sqrt{N}} |E_h E_k E_{-h-k}|$$

where N is the number of atoms in the unit cell and L is a normalization constant.

In Fig. 5, the probability distributions for different values of the parameter G_{hk} are shown to have a maximum at Φ_{hk} equal to zero and the variance decreases as G_{hk} increases.

In centrosymmetric crystals, structure factors are real numbers with phases equal to 0 (for positive) or π (for negative structure factors), and the probabilistic relationship for the triplet can be expressed as the relationship between the signs of the structure factors:

$$S(-\mathbf{h})S(\mathbf{k})S(\mathbf{h}-\mathbf{k}) \cong +$$

where $S(\mathbf{h})$ stands for the sign of the reflection $\mathbf{h}$. In this case, the basic conditional formula for sign determination is given by Cochran & Woolfson:

$$P_+ = \frac{1}{2} + \frac{1}{2} \tanh\left(\frac{1}{\sqrt{N}} |E_{-h} E_k E_{h-k}|\right)$$

The larger the absolute value of the argument of $\tanh$, the more reliable the sign indication.

For fixed $\mathbf{h}$, let the vector $\mathbf{k}$ range over the set of known values $E_k E_{-h-k}$, then the total probability distribution for ϕ_h is given by the product of the single distributions, increasing the reliability of the estimate, in mathematical terms.

Calculation of the conditional joint probability distributions for ϕ_h , under the condition that several phases ϕ_k and ϕ_{h-k} are known, leads to the tangent formula, which expresses the most likely value of the phase ϕ_h given a set of known phases of triplet invariants containing the structure factor E_h :

$$\tan \phi_h = \frac{\sum_k |E_k E_{h-k}| \sin(\phi_k + \phi_{h-k})}{\sum_k |E_k E_{h-k}| \cos(\phi_k + \phi_{h-k})}$$

This formula or its modifications and generalizations are used in almost all computer programs for phase determination by direct methods.

Fig. 5 The probability distributions for the phases of triplet invariants as a function of the parameter G .

Phase determination in practice

A typical procedure for phase determination uses a multisolution approach and for each trial, the following steps are performed:

1. Select suitable normalized structure factors and assign random values to their phases.
2. cyclically apply the tangent formula. Since this formula contains information on the positivity of the electronic density, the phases may converge to the correct values.
3. for each trial, compute a figure of merit, to estimate its quality.
4. Select the best solution out of all trials.

Phasing of large structures through direct methods with density modification

Procedures based on direct methods more or less similar to those described above are able to solve the crystal structure for small and medium size molecules (up to 200 atoms in the asymmetric unit) in a routine way, but fail for bigger molecular structures. Intuitively, it is seen that the reliability of the probability distributions for s.i.'s is an inverse function of N and as this number increases, the reliability of the relationships decreases whatever the value of the triple product of $|E|$ s. The result is that the tangent formula is inadequate for macromolecules.

In spite of these considerations, it is possible to enlarge the size of crystal structures solvable by direct methods. The key to this improvement is based on the following:

1. the cyclical use, in both real and reciprocal space, of the refinement of atomic parameters or phases;
2. electron density modification and data extrapolation;
3. methods utilizing the properties of the Fourier transform; and
4. procedure for moving a well-oriented, but misplaced structural model to the correct position.

Small proteins (up to more than 2000 non-H atoms in the asymmetric unit and with data at atomic level resolution) have been solved *ab initio* by these algorithms.

Dual space iterative algorithms

Dual-space iterative algorithms approach the phasing problem as a constraint satisfaction problem. When solving a structure from X-ray diffraction data, the experiment provides us a constraint on the electron density: the correct electron density must have the property that the amplitudes of its Fourier transform match the experimentally determined ones. This constraint is called the *amplitude constraint*. This constraint alone is not sufficient to solve the phase problem, and therefore a second constraint needs to be added. The weakest and most general constraint is the requirement for the positivity of the electron density (*positivity constraint*). Another obvious constraint follows from the fact that crystals consist of individual atoms. We could thus require that the electron density contains only a limited number of significant peaks, and the rest of the unit cell is filled by almost zero density. A weaker variant of this constraint is the mere requirement that only a small part of the unit cell has significant density, with the rest being zero. In this weaker formulation there is no explicit assumption that the significant density is grouped into separated point-like peaks (*sparseness constraint*). All these constraints are defined on the electron density rather than on its Fourier coefficients, and they are therefore direct-space constraints in contrast to the amplitude constraint, which is defined in reciprocal (Fourier) space. The fact that constraints in both spaces are used with equal importance distinguishes dual space algorithms from direct methods, which work predominantly in Fourier space. Once the constraints are defined, we may reformulate the phasing problem as follows: In the space of all possible electron densities, find the subset of densities that fulfil both the amplitude constraint and some of the direct space constraints. This subset is an intersection of the subsets fitting the amplitude constraint and the direct-space constraint.

The problem of finding an element from the intersection of two (or more) constraint sets is a well-known and thoroughly studied general problem. In the special case of convex constraint sets, well-defined iterative procedures exist, with proven convergence properties. For instance, the intersection between two convex constraint sets is always reached simply by alternating projections onto the first and the second set (Fig. 6a), where projection is a mapping from an arbitrary point ρ in the image space onto the nearest point of the constraint set C :

$$P : P(\rho) \in C \text{ and } \|P(\rho) - \rho\| = \min$$

The simplest iterative algorithm based on alternating two projections P_1 and P_2 can then be written as

$$\rho^{n+1} = P_2(P_1(\rho^n)) \equiv P_2P_1\rho^n$$

Where the last expression as a shorthand symbolic notation of applying first the projection P_1 and the P_2 to ρ^n .

In crystallography, the set associated with the amplitude constraint is unfortunately non-convex. In such case the algorithms developed for convex sets are not guaranteed to work, because they can get trapped in local minima (Fig. 6b). This drawback can be overcome by replacing simple projections by relaxed projections (overprojections), or combining these relaxed projections in more elaborate schemes. A relaxed projection R is defined as:

Fig. 6 Finding the intersection of two constraint sets. (a) Convex constraint sets and repeated projections. (b) Non-convex constraint sets and repeated projections starting from two different starting points. (c) Non-convex constraint sets and repeated overprojections.

$$R^{\gamma} = P + \gamma(P - I)$$

Where $\gamma = 1$, the superscript is usually omitted.

Fig. 6c illustrates that using relaxed projections may allow the iteration to escape from a local minimum.

Due to the non-convex nature of constraints in crystallography, no iterative algorithm has been found so far that would be guaranteed to solve the problem in finite time. Various dual space algorithms were proposed for use in crystallography (see Palatinus (2013) and Millane and Lo (2013) for review), which differ by the details of the iteration scheme as well as the details of the definition of the projections or projection-like operations used in the iteration.

Probably the best known of them is the charge flipping algorithm (Oszlányi and Sütő, 2004). Although it was not first proposed dual-space algorithm, it was the one that sparked the wide interest of the crystallographic community in this class of algorithms. The iteration scheme of the charge flipping algorithm is very simple:

$$\rho^{n+1} = P_r R_d \rho^n$$

The subscript d refers to the operation in direct space, and subscript r refers to the reciprocal space. In reciprocal space, a simple projection is used, i.e., in every iteration, the Fourier amplitudes of the current iterate are replaced by the experimental amplitudes. The constraint in the direct space is the positivity constraint with the additional modification that regions of the density that are small, but positive, are also set to zero. As the operation in direct space is a reflection, the actual operation is a multiplication of all density values below a given threshold by -1 , i.e., “flipping” the values, which gave the algorithm its name (Fig. 7).

Other important algorithms used in crystallography include:

Elser’s difference map (DM): $\rho^{n+1} = (I + \beta(P_d R_r^{\gamma_r} - P_r R_d^{\gamma_d})\rho^n$

Alternating averaged reflections (AAR): $\rho^{n+1} = \frac{1}{2}(I + R_r R_d)\rho^n$

Relaxed alternating averaged reflections (RAAR): $\rho^{n+1} = [\frac{1}{2}\beta(I + R_r R_d) + (1 - \beta)]\rho^n$

Fig. 7 (a) a simple one-dimensional density with positive and negative regions. (b) The same density after performing the charge-flipping operation, when all values below the threshold (green line) were multiplied by -1 (flipped).

A dual space algorithm dubbed *intrinsic phasing* (Sheldrick, 2015), with an iteration scheme somewhat similar to the charge flipping algorithm, but with the reflector in the reciprocal-space part, and with a very different real-space operation, is implemented in the very popular structure solution program SHELXT.

Direct space methods

Solving the phase problem directly (*ab initio*), i.e., obtaining the phases or scattering density from structure factor amplitudes, may be a difficult problem. If, however, not enough amplitudes are known, or if not individual amplitudes, but only some of their combinations are known, the problem is essentially impossible to solve. It is, however, a relatively easy task to verify, if a proposed solution fits the experimental data, and to compare, which of two proposed solutions fits the data better. This is the basis of the direct space methods, called sometimes also global optimization methods. They are being used mostly in connection with powder diffraction data, where the whole three-dimensional diffraction pattern is projected into a one-dimensional profile of intensity against the diffraction angle (cf. Fig. 1b), and thus reflections may overlap and individual intensity information is lost. However, the same technique may be applied also to any other diffraction data in case of need.

The basic principle of all direct space methods is generating trial crystal structures and comparing the data calculated from them with experimental data. The best trials are retained and, using the information about the past trials, new set of trials is generated in the next iteration.

The complexity of the task grows exponentially with the number of free parameters (degrees of freedom) of the structure. A structure with N atoms has, in general, $3N$ degrees of freedom—one for each coordinate of each atom in the structure. This number quickly becomes prohibitively large even for moderately large structures. The situation becomes more tractable, if the structure contains known and well-defined chemical motifs, such as a molecule with known connectivity. In case of a single molecule in the asymmetric unit of the crystal, the number of degrees of freedom is $6 + idf$, where the six degrees of freedom come from the three translations and three rotations of the molecule, and *idf* stands for internal degrees of freedom, which are typically only the molecular torsion angles, as the bond lengths and bond angles are usually well known for organic molecules (Fig. 8).

The key to the success of the structure solution by direct space methods is the algorithm for generating the trials. The algorithm must be able to sample the search space effectively, while converging quickly to the best solution once a trial in its vicinity is found. The two most studied and most used approaches to the problem are simulated annealing (with its variant parallel tempering) and genetic algorithms.

Genetic algorithms

As the name implies, genetic (or evolutionary) algorithms are inspired by natural processes occurring during evolution. Genetic algorithm is a global optimization algorithm based on generating a set of trial structures (parents) and using their quality (fitness) to generate a new, more fit generation (offspring).

The basic steps of genetic algorithms adapted to crystallographic problems are the following (Shankland et al., 1997; Kariuki et al., 2001):

- (1) generate a random set of N_p trial structures—the parent generation
- (2) use “mating algorithm” to generate a set of N_o offspring. The mating procedure combines the parameters of two parents generating the offspring, like the position of the molecule, its orientation and values of the degrees of freedom.

Fig. 8 Molecule of paracetamol with torsion angles outlined. Although the molecule has 10 non-hydrogen atoms, only two torsion angles need to be determined in the structure solution process. Note that the additional two torsion angles (gray without labels) are irrelevant for the solution process, because hydrogen atoms are weak scatterers, and they can be usually ignored in the structure solution step.

- (3) Use “mutation algorithm” to generate N_m mutants, either only from the offspring or from both the parents and offspring. In a mutation one or a larger number of parameters are changed. The change may be to a completely random new value, or a random change of the previous value may be used.
- (4) Select the $(N_p - N_m)$ trials from the set of $N_p + N_o$ trials using a suitable cost function that evaluates the match of these trials to the experimental data. The best trials should be selected, but not only the best ones. With some probability, less good trials are also selected to maintain the diversity of the population.
- (5) Combine the $(N_p - N_m)$ selected trials with N_m mutants to obtain a new generation of parents. Note that copying some of the parents into a new generation is not following the natural evolution process. However, this procedure, called elitism, proved to be essential for the success of the algorithm.

Typically, the size of the population in one generation (N_p) is a few hundred, and it can take a few thousand generations to converge to the solution. Many variants of genetic algorithms can be created and have been tested, which differ by the way offspring is generated, mutations are computed and the next generation of trials is generated.

Simulated annealing

Like genetic algorithms, simulated annealing is a general algorithm for global optimization problems. It is inspired by the process of physical annealing, where the temperature is elevated first and then it is progressively lowered and in the process the system has the possibility to explore the energy landscape and find global energy minimum.

In the structure solution process, the role of temperature is to increase or decrease the probability of a less optimal trial to be accepted in the next set of trials. The basic algorithm of simulated annealing can be outlined as follows (David et al., 1998):

- (1) Generate a set of random trials that sample the global parameter space effectively.
- (2) Set a starting temperature T .
- (3) Apply a random change to the parameters of each trial structure.
- (4) Evaluate the cost function C for each trial. The cost function may include not only the match to the experimental data, but also other criteria, e.g., chemical or geometric, like connectivity, coordination numbers, bond angles. . .
- (5) If the cost function is lowered after the random move, accept the new trial structure and reject the old one. If the cost function increases, accept the new trial with the probability proportional to $\exp(-\frac{\Delta C}{T})$, where ΔC is the difference between the cost function values after and before the modification.
- (6) Repeat the procedure, while progressively lowering T , until convergence.

We can see that the higher the temperature, the larger the probability that a change with positive ΔC will be accepted. This ensures that the system can escape local minima and explore the parameter landscape. As the temperature lowers, the system tends to settle into broad minima and progressively converge to the best structure inside these minima. In simulated annealing, the number of trials in one iteration cycle can reach many thousands. Here again, many variants and improvements of the basic simulated annealing procedure have been proposed and used. The one worth a special mention is *parallel tempering*, which differs from the standard algorithm by running the calculation at several temperatures at the same time and exchanging the trials between the temperatures rather than lowering the temperature for the whole set of trials.

Phasing methods for low-resolution diffraction data

Ab initio phasing methods are all based on the assumption of existence of discrete maxima in the scattering density. As the maximum spatial frequency of the available Fourier amplitudes decreases, the Fourier transform becomes more and more “blurry,” until it is not composed of discrete maxima anymore. In such case, ab initio methods cannot be used, and if the size of the structure is large, direct space methods are also not feasible. This is frequently the case in macromolecular crystallography, especially in the structure determination of proteins. In these cases, the structures can be either solved by experimental approaches like single/multiple isomorphous replacement or single/multiple anomalous dispersion, or by a technique called molecular replacement, where a starting model is obtained by placing a known (or estimated) fragment of the molecule in the unit cell. See Mueller and Weiss (2023) for details on these techniques.

Conclusion

Numerous algorithms have been devised to solve the key step in crystal structure analysis—the assignment of the phases to the structure factors, and, as a consequence, the determination of positions of atoms in the crystal structure. The availability of these algorithms is one of the corner stones of the immense success of crystallography in the past century, with well over a million determined and published crystal structures. The constant development of the algorithms turned the solution of the phase problem in many cases to a routine and fast procedure performed automatically by specialized software. However, there are still problems that are hard to tackle and that require substantial effort. Further improvements of the structure solution algorithms are thus desirable. The next revolution in this utterly practical and important field may be around the corner thanks to the quickly developing field of machine learning/artificial intelligence.

Abstract

Despite recent advances in other structure determination methods, such as for instance cryo-electron microscopy, macromolecular X-ray crystallography is still by far the most popular experimental method for determining the three-dimensional structure of biological macromolecules. More than 80% of all macromolecular structures determined to date, have been determined by crystallography. The physical principle behind X-ray crystallography is the elastic scattering of electromagnetic waves by the crystalline sample. The resulting three-dimensional diffraction pattern is recorded and analyzed. It contains the information on the spatial structure of the crystallized molecule, although the structure itself is not directly available from the diffraction pattern. The fact that only the amplitudes but not the phases of the X-ray reflections can be measured is also known as the crystallographic phase problem, which has to be solved before the structure can be determined.

Key points

- Despite recent advances in other structure determination methods, such as for instance cryo-electron microscopy, macromolecular X-ray crystallography is still by far the most popular experimental method for determining the three-dimensional structure of biological macromolecules.
- More than 80% of all macromolecular structures determined to date, have been determined by crystallography.
- The physical principle behind X-ray crystallography is the elastic scattering of electromagnetic waves by the crystalline sample.
- The resulting three-dimensional diffraction pattern is recorded and analyzed. It contains the information on the spatial structure of the crystallized molecule, although the structure itself is not directly available from the diffraction pattern.
- The fact that only the amplitudes but not the phases of the X-ray reflections can be measured is also known as the crystallographic phase problem, which has to be solved before the structure can be determined.

Nomenclature

$\vec{f}(\vec{s})$	Atomic form factor
$\vec{F}(\text{hkl})$	Structure factor for reflection (hkl)
$ \vec{F}(\text{hkl}) $	Structure factor amplitude for reflection (hkl)
$\alpha(\text{hkl})$	Phase for reflection (hkl)
$I(\text{hkl})$	Intensity of reflection (hkl)

[☆]Change History: September 2022. U Mueller and MS Weiss updated all sections.

$\rho(x,y,z)$	Electron density at the point (x,y,z) in the unit cell; x , y and z are fractional coordinates and the unit of ρ is $e/\text{\AA}^3$ ($1 \text{ \AA} = 10^{-10} \text{ m}$).
$P(uvw)$	Patterson function value at position (u,v,w)

Introduction

Since its advent in 1914 when W. L. Bragg and W. H. Bragg managed to determine the three-dimensional structure of table salt based on the observed X-ray reflection intensities, X-ray crystallography or crystal structure determination by means of X-ray diffraction has become one of the fastest growing fields in chemistry, biochemistry and material science. Nearly everything that is known today with respect to how atoms arrange themselves into molecules has its origin in crystal structures. At the time of writing this chapter in the beginning of 2022, more than 250,000 inorganic crystal structures had been deposited in the Inorganic Crystal Structure Data Base (ICSD), nearly 1,200,000 molecular structures in the Cambridge Structural Data Base (CSD), and almost 200,000 structures of biological macromolecules in the Protein Data Bank (PDB) (Bruno et al., 2017). In present days, research fields ranging from physics to chemistry, mineralogy, geology, material science, metallurgy all the way to biology, pharmacy, and medicine embrace crystal structure determination as one of their most essential and relevant techniques. In this chapter, a brief introduction into crystal structure analysis will be given with a focus on biological macromolecules. The chapter will describe the principles of the technique rather than the more practical aspects. It should give the interested reader sufficient detail and background, so that more elaborate and more comprehensive texts (Blundell and Johnson, 1976; Drenth, 1994; Giaccovazzo et al., 1992; Glusker and Trueblood, 1985; Ladd and Palmer, 1994; Rhodes, 1993; Rupp, 2009; Stout and Jensen, 1968) can be read and understood.

Text

A complete description of X-ray crystallography as an experimental structure determination technique requires an in-depth discussion of the two main parts of the crystallographic experiment. At first, the relationship between the object to be studied and its corresponding diffraction pattern must be derived and understood. Then, the way back from the diffraction pattern to the structure has to be outlined and described.

Part 1. From objects to diffraction patterns

The scattering equation

Electromagnetic waves interact with matter. Their electric components force charged particles to oscillate with the same frequency as the incident wave. Oscillating electrons constitute moving charges, and moving charges emit electromagnetic radiation of the same frequency into all directions of space. This phenomenon is called *elastic scattering*, *Thomson scattering* or *scattering without loss of energy*. Atomic nuclei interact with electromagnetic waves in the very same way as electrons, but since a proton is about 2000 times heavier than an electron, and thus much less prone to be moved, the scattering by nuclei can be neglected for the purposes of X-ray crystallography. The mathematical description of the phenomenon of scattering is illustrated in Fig. 1.

The incoming X-ray wave (from the left) is represented by the vector $\vec{s}_{\text{in}}$ with $|\vec{s}_{\text{in}}| = 1/\lambda$ where λ is the wavelength of the incoming X-ray wave. The wave impinges upon the object and is then scattered by the whole object, in all directions of space. For simplicity, only the scattering at the points O and P is considered now, and only the scattering in the direction described by $\vec{s}_{\text{out}}$. $\vec{s}_{\text{out}}$ is a vector representing the scattered wave ($|\vec{s}_{\text{out}}| = 1/\lambda$). The difference vector between $\vec{s}_{\text{out}}$ and $\vec{s}_{\text{in}}$ ($\vec{s}_{\text{out}} - \vec{s}_{\text{in}}$) is called the scattering vector $\vec{s}$. The scattering vector describes the change in direction the X-ray wave undergoes upon scattering. The size of the object, i.e., the distance between points O and P in the example given here leads to a path difference $\Delta x = \vec{r}(\vec{s}_{\text{out}} - \vec{s}_{\text{in}}) \cdot \lambda = \vec{r} \cdot \vec{s} \cdot \lambda$ between the two scattered waves shown in Fig. 1. This path difference results in a phase difference $\Delta\alpha = \Delta x \cdot 2\pi/\lambda = 2\pi \vec{r} \cdot \vec{s}$ between the two scattered waves. The wave scattered at point P has an amplitude proportional to the electron density $\rho(P)$ at point P and a phase of $2\pi \vec{r} \cdot \vec{s}$ relative to the wave scattered at point O. In order to compute the total wave $\vec{f}_T$ scattered by the object depicted in Fig. 1, an integration over all volume elements (V) of the scattering object has to be performed. This leads to the general scattering

Fig. 1 Scattering of electromagnetic waves by an object.

equation (Eq. 1). $\vec{f}_T(\vec{s})$ describes the scattering by every conceivable object, which can be described by $\vec{r}$, $\rho(\vec{r})$, and V , into the direction defined by the vector $\vec{s}$.

$$\vec{f}_T(\vec{s}) = \int_{\text{Vol}} \rho(\vec{r}) e^{2\pi i \vec{r} \cdot \vec{s}} dV \quad \text{Scattering Equation} \quad (1)$$

Eq. (1) can also be regarded as a *Fourier Analysis* of the object to be studied by the X-rays.

Scattering by atoms and molecules

The description of the scattering of real atoms starts from the general scattering equation (Eq. 1). The integration over the whole volume V of the atom implies that the function $\vec{f}(\vec{s})$ is dependent on the form of the electron cloud of the atom. It is therefore also called the *Atomic Form Factor*. The atomic form factor is an intrinsic property of an atom or ion, which depends on the exact architecture of the electron cloud of the atom or the ion. Atomic form factors can be calculated using quantum mechanical approximations from the electron distribution of the atoms or ions, but they can also be measured very accurately for instance by X-ray scattering.

The scattering by a molecule can now simply be calculated based on the scattering of the atoms belonging to the molecule (Fig. 2a). The total scattered wave is the sum of the individually scattered waves in any given direction (Fig. 2b). Using the example of a three-atom molecule, the contributions by the three atoms have to be considered: $\vec{F}_1 = \vec{f}_1(\vec{s}) e^{2\pi i \vec{r}_1 \cdot \vec{s}}$ for atom 1, $\vec{F}_2 = \vec{f}_2(\vec{s}) e^{2\pi i \vec{r}_2 \cdot \vec{s}}$ for atom 2 and $\vec{F}_3 = \vec{f}_3(\vec{s}) e^{2\pi i \vec{r}_3 \cdot \vec{s}}$ for atom 3. The result is shown in Eq. (2). It is also called the *Molecular Transform*.

$$\vec{F}_m(\vec{s}) = \sum_{j=1}^3 \vec{f}_j(\vec{s}) e^{2\pi i \vec{r}_j \cdot \vec{s}} \quad \text{Molecular Transform} \quad (2)$$

$\vec{f}_j(\vec{s})$ are the atomic form factors and $\vec{r}_j$ the coordinates of the corresponding atoms j .

Scattering by a crystal

A crystal is defined as a solid object, which is periodic in three dimensions. In order to build up a crystal from its smallest unit, the unit cell, one just needs to know the contents of the unit cell and the so-called lattice translations $\vec{a}$, $\vec{b}$ and $\vec{c}$. For describing the scattering of one single unit cell of a crystal, $\vec{F}_{\text{unit cell}}(\vec{s})$, the contributions of all N atoms in the unit cell have to be added up (Eq. 3).

$$\vec{F}_{\text{unit cell}}(\vec{s}) = \sum_{j=1}^N \vec{f}_j(\vec{s}) e^{2\pi i \vec{r}_j \cdot \vec{s}} \quad (3)$$

Further on, in order to consider the scattering by the whole crystal now, the contributions of all unit cells of the crystal and all atoms in each unit cell have to be taken into account. Let $\vec{F}_{\text{unit cell}}(\vec{s})$ be the scattering of the first unit cell, and $\vec{F}'_{\text{unit cell}}(\vec{s})$ the scattering of a second unit cell shifted by $\vec{r} = u\vec{a} + v\vec{b} + w\vec{c}$ relative to the first unit cell (u , v , and w are integer values, and $\vec{a}$, $\vec{b}$, and $\vec{c}$ are the lattice translations) (Fig. 3a). It can be shown that the contribution of the second unit cell can be expressed as the scattering of the first unit cell and the vector that relates the two unit cells.

$$\vec{F}'_{\text{unit cell}}(\vec{s}) = \vec{F}_{\text{unit cell}}(\vec{s}) e^{2\pi i u \vec{a} \cdot \vec{s}} e^{2\pi i v \vec{b} \cdot \vec{s}} e^{2\pi i w \vec{c} \cdot \vec{s}} \quad (4)$$

To arrive at the scattering equation for the whole crystal, the sum over all unit cells has to be calculated. This can be reduced to summing over all combinations of u , v , and w .

$$\vec{F}_{\text{Crystal}}(\vec{s}) = \vec{F}_{\text{unit cell}}(\vec{s}) \sum_{u=0}^{n_1} e^{2\pi i u \vec{a} \cdot \vec{s}} \sum_{v=0}^{n_2} e^{2\pi i v \vec{b} \cdot \vec{s}} \sum_{w=0}^{n_3} e^{2\pi i w \vec{c} \cdot \vec{s}} \quad (5)$$

n_1 , n_2 and n_3 are the numbers of the unit cells in the respective $\vec{a}$ -, $\vec{b}$ - and $\vec{c}$ -directions. These numbers are large for typical crystals in the μm - to mm -size range. This means that the sums $\sum_{u=0}^{n_1} e^{2\pi i u \vec{a} \cdot \vec{s}}$, $\sum_{v=0}^{n_2} e^{2\pi i v \vec{b} \cdot \vec{s}}$, and $\sum_{w=0}^{n_3} e^{2\pi i w \vec{c} \cdot \vec{s}}$ will be zero unless $\vec{a} \cdot \vec{s}$, $\vec{b} \cdot \vec{s}$, and $\vec{c} \cdot \vec{s}$ are

Fig. 2 (a) Scattering by a schematic three-atom molecule. Each of the three atoms contains a different number of electrons, (b) Argand diagram with the vector addition of the three individually scattered waves yielding the Molecular Transform.

Fig. 3 (a) Two unit cells of a crystal, (b) Graphical representation of the Laue conditions in one dimension. In the case shown, the scalar product $\vec{a} \cdot \vec{s} \neq h$. As a result of this, the waves with different values of u exhibit phase differences $\neq 2\pi$. Due to the large number of waves to be considered (one for each unit cell of the crystal), the overall sum will be zero.

integral numbers. These conditions are also known as the *Laue Conditions* and they are illustrated in Fig. 3b as vector additions in an Argand diagram. In the case of the Laue conditions being fulfilled, the product of the three sums is equal to the total number of unit cells in a given crystal.

This derivation bears two important consequences. First, the scattering of a crystal is proportional to the scattering of just one unit cell and the total number of unit cells in the crystal. Consequently, in order to describe the scattering by the whole crystal, it is sufficient to consider the scattering by just one unit cell. Second, the scattering of a crystal leads to a discrete diffraction pattern. Only in those directions $\vec{s}$, in which the Laue conditions are obeyed, scattering will be observed. In all other directions the sum of all scattered waves will be zero. This leads to the observation of a diffraction pattern consisting of discrete maxima, the so-called X-ray reflections. Each reflection is identified by a unique combination of the three numbers h , k , and l , the Miller indices.

$$\vec{F}_{\text{Crystal}}(\vec{s}) = n \vec{F}_{\text{unit cell}}(\vec{s}) = n \sum_{j=1}^N \vec{f}_j(\vec{s}) e^{2\pi i \vec{r}_j \cdot \vec{s}} \quad (n : \text{number of unit cells}) \quad (6)$$

With $\vec{r}_j = x_j \vec{a} + y_j \vec{b} + z_j \vec{c}$ (x_j , y_j , and z_j are the fractional coordinates of atom j), and with the Laue conditions $\vec{a} \cdot \vec{s} = h$, $\vec{b} \cdot \vec{s} = k$, and $\vec{c} \cdot \vec{s} = l$, Eq. (6) can be transformed into Eq. (7).

$$\vec{F}(\vec{s}) = \vec{F}(hkl) = \sum_{j=1}^N \vec{f}_j e^{2\pi i (hx_j + ky_j + lz_j)} \quad (7)$$

Eq. (7) is also called the *Structure Factor Equation*. It constitutes the first of the two central equations in X-ray crystallography, the second one being the *Electron Density Equation* (see below). The Structure Factor Equation describes the scattering of a crystal defined by the unit cell vectors $\vec{a}$, $\vec{b}$, and $\vec{c}$, and by the atoms inside the unit cells of this crystal as defined by their atomic form factors (f_j) and their fractional coordinates (x_j , y_j , and z_j).

The diffraction experiment

A schematic representation of an X-ray experiment is shown in Fig. 4. The experiment itself involves the production or generation of X-rays, the selection of the X-rays for the experiment, the preparation of the crystal for the experiment, the actual data collection step and the processing and validation of the resulting data. Of course, if one is just interested in using X-rays to determine a crystal structure one may not be overly concerned with the way X-rays are produced and prepared for the measurement, but there are some

Fig. 4 Schematic representation of the diffraction experiment. Depicted are the X-ray source, the object (crystalline sample) mounted on a rotatable device and the detector for detecting the scattered waves.

important aspects that can potentially have a great impact on the quality of the obtained diffraction data and consequently on various stages of structure determination and certainly on the information content of the resulting structure. One should always keep in mind that the quality or the information content of a crystal structure is directly determined by the quality or the information content of the diffraction data that are the basis for the determination of the structure. Furthermore, the collection of diffraction data is the last real experimental step to be carried out in the course of a crystal structure analysis. Everything after that is merely a computer-based interpretation of the collected diffraction data.

Part 2. From the diffraction pattern to the structure

The electron density equation

The Fourier transformation of the general scattering equation (Eq. 1) leads to the electron density equation (Eq. 8), the second central equation in X-ray crystallography. Instead of integrating over the volume of the scattering object V , the integration proceeds now over diffraction space V^* , which is sometimes also called reciprocal space, because of the reciprocal relationship to the real space with respect to its geometric parameters.

$$\rho(\vec{r}) = \int_{V^*} \vec{F}(\vec{s}) e^{-2\pi i \vec{r} \cdot \vec{s}} dV^* \quad \text{Electron Density Equation} \quad (8)$$

Similar to regarding Eq. (1) as a *Fourier Analysis* of the object, Eq. (8) can be regarded as a *Fourier Synthesis*. The object can be reconstructed from its diffraction pattern by taking into account all scattered waves. A simpler version of the electron density equation (Eq. 9) can be derived considering that the diffraction pattern of a crystal is discrete (see above), and that instead of integrating over the whole volume of diffraction space, we only need to sum over the observed X-ray reflections.

$$\rho(x, y, z) = \sum_{h,k,l} |\vec{F}(hkl)| e^{-2\pi i(hx+ky+lz)+i\alpha(hkl)} \quad (9)$$

Eq. (9) demonstrates two points. First, in order to calculate the value for the electron density ρ at any given point (x,y,z) in the unit cell, all reflections have to be taken into account. Second, the summation can only be carried out if both the structure factor amplitude $|\vec{F}|$ and the phase α are known for each reflection (hkl) .

The phase problem

The data which are obtained from a diffraction experiment are the intensities I of the reflections (hkl) . The intensity $I(hkl)$ can be calculated by multiplying the structure factor $\vec{F}(hkl)$ with its conjugated complex structure factor $\vec{F}^*(hkl)$. The net result is that $I(hkl)$ is proportional to the square of the structure factor amplitude $|\vec{F}(hkl)|$ (Eq. 10).

$$I(hkl) \propto |\vec{F}(hkl)| |\vec{F}^*(hkl)| = |\vec{F}(hkl)| e^{i\alpha(hkl)} |\vec{F}(hkl)| e^{-i\alpha(hkl)} = |\vec{F}(hkl)|^2 \quad (10)$$

As a consequence, by having measured the X-ray intensities, we are only able to back-calculate the amplitudes $|\vec{F}(hkl)|$ of the waves. The information about the phases $\alpha(hkl)$ is lost. This is known as the so-called *phase problem* in crystallography. The phase problem is the reason why an image of the molecule to be studied cannot be calculated directly from the diffraction data. Approaches to overcome the problem will be briefly discussed in the next chapter.

Crystallographic phase determination

Over time several methods have been developed to address the crystallographic phase problem. The decision as to which method to use is more or less governed by both the size of the molecules to be studied and the diffraction power of the corresponding crystals. For the crystallography of small molecules, i.e., molecules of up to a few hundred atoms, where the crystals typically exhibit very good diffraction properties, the so-called *direct methods* are the method of choice. These have nowadays been mostly automated and thus also made available to the non-expert user so that crystal structure determination of small molecules can be considered a routine feat. In macromolecular crystallography where the molecules are much larger and where the corresponding crystals typically exhibit limited diffraction properties, the method of choice nowadays is the so-called *molecular replacement* method. While up to a few years ago, methods based on *isomorphous replacement* or on the exploitation of *anomalous scattering* have been the most important methods for *de novo* structure determination of biological macromolecules, the advent of the structure prediction program AlphaFold2 has completely shifted the focus from those methods toward molecular replacement. For the sake of completeness, all of the mentioned approaches will be discussed in brief.

Molecular replacement

The method of molecular replacement relies on the availability of a molecular structure, which is similar to the unknown structure to be solved. The known structure can be computationally placed into the unknown structure's unit cell, and initial structure factors $\vec{F}_p$ can be calculated. Although these first calculated amplitudes $|\vec{F}_p|$ and phases α_p will not be correct, they may be used as starting values for further refinement.

In 2020, DeepMind researchers announced and published the solution to a 50-years old grand challenge in biochemical structural science: the sequence-structure relationship. By designing a deep learning algorithm into the neural network AlphaFold2, the three-dimensional structure of any given protein can be determined, using just its amino acid sequence as input (Jumper et al., 2021). Consequently, a fairly accurate and reliable computational model for nearly any protein's three-dimensional structure can be

Fig. 5 Schematic view of a structure determination by molecular replacement using an AlphaFold2 predicted structure.

derived. This can then be used in a molecular replacement approach to determine the crystallographic structure from experimental data (McCoy et al., 2022).

Although the experimental structure may differ in some aspects from the model structure, the structural models derived from AlphaFold2 are usually similar enough to the final experimental structures, so that they can successfully be used as starting models for molecular replacement (Fig. 5).

A structure determination by molecular replacement is a six-dimensional problem. The known structure (referred to as the *search model*) needs to be properly oriented and placed in the unit cell of the crystal structure to be determined (referred to as the *target structure*). This requires three rotational and three translational parameters to be determined. This six-dimensional problem can be conveniently broken down into two three-dimensional problems.

Molecular replacement relies on the properties of the Patterson function (Eq. 11), which is essentially a Fourier Transform of the diffraction intensities. It can be calculated directly from the intensity data $I(hkl)$ (or the square of structure factor amplitudes), without the need of the X-ray reflection phases $\alpha(hkl)$

$$P(uvw) = 1/V \sum_{hkl} \left| \vec{F}(hkl) \right|^2 e^{-2\pi i(hu + kv + lw)} \quad \text{Patterson Function} \quad (11)$$

Here, u , v , and w are the coordinates in Patterson space. Since the Patterson Function $P(uvw)$ is equivalent to a convolution of the electron density $\rho(x,y,z)$ (Eq. 9) with itself (Eq. 12), maxima in $P(uvw)$ correspond to vectors between peaks in $\rho(x,y,z)$. Similarly, a Patterson map derived from a structure with N atoms, exhibits $N(N-1)$ peaks. These peaks represent all interatomic vectors between atoms of the structure.

$$P(uvw) = \int_{x,y,z} \rho(x, y, z) * \rho(u+x, v+y, w+z) dx dy dz \quad (12)$$

In the first step of the molecular replacement procedure, the Patterson map of the search model is compared in all different orientations with the Patterson map derived from the experimental diffraction data. A maximum in the so-called rotation function determines the correct orientation of the search model. In a second step, the correctly oriented search model is translated through the entire unit cell, and the position is sought at which the discrepancy between model-derived data and experimental data is minimal. This so-called translation function determines the correct position of the search model in the unit cell of the target structure.

Isomorphous replacement

Historically the most relevant phase determination method in macromolecular crystallography is isomorphous replacement. In this method, diffraction data sets of two isomorphous crystals are compared with each other reflection by reflection. The first crystal may be the one of a native macromolecule, the second crystal may be one of a heavy atom derivative of the same macromolecule. This latter one can be prepared by either co-crystallization or soaking a native macromolecule crystal in a heavy atom containing solution. A detailed comparison of the two diffraction data sets will then in a first step yield the differences between the data sets, which are due to the heavy atom substructure. From these differences, the substructure can be determined. With the substructure at hand, one can then calculate the structure factor amplitude and the phase of just the substructure, and then use this heavy atom phase as a reference to calculate the phases of the reflections of the macromolecule crystal. An easy way to visualize this is a vector diagram (Fig. 6). The vector addition of the structure factor of the macromolecule alone $\vec{F}_P$ and the structure factor of the heavy atoms alone $\vec{F}_H$ will yield the structure factor of the heavy atom derivative $\vec{F}_{PH}$. If we know now the magnitude of both $\vec{F}_P$ and $\vec{F}_{PH}$ (these are the structure factor amplitudes which have been measured in the two diffraction experiments) and the magnitude and

Fig. 6 Vector addition of the structure factors for the native macromolecule $\vec{F}_P$, the heavy atom substructure $\vec{F}_H$ and the heavy atom derivative of the macromolecule $\vec{F}_{PH}$.

direction of $\vec{F}_H$ (this can be calculated once the heavy atom substructure is known), all other parameters of the triangle in Fig. 6 can be calculated as well.

However, this vector addition is not unambiguous. The result of this calculation will not be a unique phase $\alpha(hkl)$ for a given reflection, but two possible solutions, which are symmetrical about the vector $\vec{F}_H$. This situation can be made unambiguous, for instance by including a second heavy atom derivative or by including anomalous scattering information.

Anomalous diffraction

Anomalous scattering occurs when the energy of the X-rays used for the diffraction experiment is close to an elemental X-ray absorption edge. If the structure to be determined contains such anomalous scatterers, a diffraction experiment can be carried out at two (or more) different X-ray energies. The differences between the diffraction patterns can then again be attributed to the anomalously scattering substructure, and in the same way as above, the substructure can be determined, and the substructure phase be used as a reference to determine the phase α_P . Important realizations of this approach have been the so-called MAD (multiple wavelength anomalous diffraction) or SAD (single wavelength anomalous diffraction) methods.

Direct methods

The direct methods rely on the principle that the phase information is somehow included in the measured structure factor amplitudes. The underlying rationale is that structure factors are not independent of each other but that they are related through the structure. With the additional constraints that (i) the electron density can never be negative and that (ii) the structure to be determined consists of discrete atoms, phase sets can be constructed randomly and examined with respect to their validity.

The credibility of a given set of phases can be examined by considering probabilistic relationships between the phases of certain reflections, e.g., the *triplet invariants* (Eq. 13). It can be derived, that the phases of the three reflections (h_1, k_1, l_1) , (h_2, k_2, l_2) and $(-h_1-h_2, -k_1-k_2, -l_1-l_2)$ are related by the following equation:

$$\alpha(h_1, k_1, l_1) + \alpha(h_2, k_2, l_2) + \alpha(-h_1-h_2, -k_1-k_2, -l_1-l_2) \approx 0 \quad (13)$$

This equation is not absolutely but only approximately valid, and it is usually formulated as a probability. The stronger the three reflections (h_1, k_1, l_1) , (h_2, k_2, l_2) and $(-h_1-h_2, -k_1-k_2, -l_1-l_2)$ are, the higher the probability that the three phase values sum up to zero or an integral multiple of 2π .

Various measures to evaluate the quality of a given phase set have been introduced over time. The most widely known formula for this purpose is the *tangent formula* (Eq. 14). In this formula, the most probable value of the phase of one reflection $\alpha(h_1, k_1, l_1)$ is given as a function of the values of the phases of all other reflections (h_m, k_m, l_m) and $(-h_1-h_m, -k_1-k_m, -l_1-l_m)$, which share a triplet invariant with (h_1, k_1, l_1) . The reliability of the formula depends on the magnitude of the structure factor amplitudes of the reflections considered.

$$\tan[\alpha(h_1, k_1, l_1)] = \frac{\sum_i W_m \sin[-\alpha(h_m, k_m, l_m) - \alpha(-h_1-h_m, -k_1-k_m, -l_1-l_m)]}{\sum_i W_m \cos[-\alpha(h_m, k_m, l_m) - \alpha(-h_1-h_m, -k_1-k_m, -l_1-l_m)]} \quad (14)$$

Tangent Formula

The two sums in the numerator and the denominator run over all possible triplet invariants i , in which the reflection (h_1, k_1, l_1) is involved, and the numbers W_m describe the weighted product of the normalized structure factor amplitudes of reflections (h_m, k_m, l_m) and $(-h_1-h_m, -k_1-k_m, -l_1-l_m)$.

Relationships such as the triplet invariants and the tangent formula help to reduce the complexity of the phase set. Nevertheless, because of the large number of possible phase sets, direct methods for phase determination are typically only applicable to small structures.

Model building and refinement

Once initial phases have been determined by one of the methods described above, the electron density distribution can be calculated according to Eq. (9). The electron density is nothing but an image of the structure to be determined. It shows where in the unit cell the electrons (hence the atoms) are. Since molecular structures are usually described by the position of all of its atoms, the electron density has to be interpreted in terms of atomic positions and identities. Finally, the so obtained model can be subjected to a mathematical optimization procedure called refinement, in order to optimize the fit between the structure factors that can be calculated from the model and the ones that have been observed experimentally. This constant feedback between model and experimental data is one of the greatest strengths of the X-ray crystallography.

Conclusion

The aim of this chapter was to provide a basic and concise introduction into the method and the principles of X-ray crystallography of biological macromolecules. While we realize that other structure determination methods exist and continue to be developed further, we are convinced that X-ray crystallography will remain the dominant method for structure determination for many years to come. This is owed first and foremost to its capacity to result in structures to atomic resolution or sometimes even better, and second to its high degree of development, both on the instrumental and on the computational side, which lends itself to automation. This in turn makes the method accessible to experts and non-experts alike. Last but not least, due to the high information content of each individual structure, X-ray crystallography will continue to be used by many researchers in many different research fields.

Abstract

Definition: A group G is a set of N elements g_i with a composition law ("multiplication" $g_i \circ g_j$) of any two elements g_i and $g_j \in G$ obeying the following four group axioms:

1. The "product" of any two group elements g_i and $g_j \in G$ is again an element of the group: $(g_i \circ g_j) = g_k \in G$ (axiom of closure).
2. There exists always a neutral element (identity) e , such that $(e \circ g_i) = (g_i \circ e) = g_i$ for any $g_i \in G$.
3. For every $g_i \in G$, there exists an inverse element $g_i^{-1} \in G$ such that $(g_i \circ g_i^{-1}) = (g_i^{-1} \circ g_i) = e$.
4. For any three elements $g_i, g_j, g_k \in G$, the associative law holds: $(g_i \circ g_j) \circ g_k = g_i \circ (g_j \circ g_k)$.

Nomenclature

$-\sigma$	Hydrostatic pressure
$N(G) = G $	Order of group G
G	Point group of a crystal
$\mathcal{H}$	Subgroup
$\mathcal{P}$	Symmetry group of the property P
$[i]$	Index of a subgroup or supergroup; number of orientation states of domains
e	Neutral element, identity
F	External physical influence (external field) on a crystal
g_i	Element of G
p	Electric polarization vector, pyroelectric vector
P	Physical (tensor) property of a crystal
W	(3×3) matrix of a point-group operation
σ_{ii}, σ_{ij}	Uniaxial stress, shear stress

Brief review of groups

Definition: A group G is a set of N elements g_i with a composition law ("multiplication" $g_i \circ g_j$) of any two elements g_i and $g_j \in G$ obeying the following four group axioms:

1. The "product" of any two group elements g_i and $g_j \in G$ is again an element of the group: $(g_i \circ g_j) = g_k \in G$ (axiom of closure).
2. There exists always a neutral element (identity) e , such that $(e \circ g_i) = (g_i \circ e) = g_i$ for any $g_i \in G$.
3. For every $g_i \in G$, there exists an inverse element $g_i^{-1} \in G$ such that $(g_i \circ g_i^{-1}) = (g_i^{-1} \circ g_i) = e$.
4. For any three elements $g_i, g_j, g_k \in G$, the associative law holds: $(g_i \circ g_j) \circ g_k = g_i \circ (g_j \circ g_k)$.

The finite number N of (different) elements of a group is the order of the group (finite groups). If the group contains infinitely many (different) elements, the group is said to be of infinite order (infinite group).

A finite group G is called cyclic, if it can be generated by one element $g: g^1 = g, g^2, g^3, \dots, g^N = e$ and is of order N .

If the relation $(g_i \circ g_k) = (g_k \circ g_i)$ holds for all pairs $g_i, g_k \in G$, the group is called commutative or Abelian. All groups containing only binary elements g_i (i.e., $g_i \circ g_i = g_i^2 = e$, or equivalently, $g_i = g_i^{-1}$) and all cyclic groups are commutative.

A subset H of a group $G, \mathcal{H} \subset G$, is called a subgroup of G , if H obeys the group axioms. In this case, G is a supergroup of H . For finite groups, the ratio of the orders of group and subgroup, $N(G)$ and $N(\mathcal{H})$, is the index $[i]$ of H in G : $[i] = N(G)/N(\mathcal{H}) = |G|/|\mathcal{H}|$. According to the theorem of Lagrange, for finite groups the index $[i]$ is always an integer.

An illustrative representation of a finite group G of order N is the multiplication table or group table of $G = \{e, g_2, g_3, g_4, \dots, g_N\}$. It is an $(N \times N)$ square array of all products according to the abstract scheme of Table 1. Note that in each of the N rows and N columns of the table, each group element appears exactly once.

Groups of the same order and with the same structure of the group table, that is, with strict correspondence of their ordered elements and their products (irrespective of the names and symbols of the group elements), are isomorphic. If the group table is symmetric with respect to the main diagonal, the group is commutative.

In crystallographic groups, the group elements are symmetry operations (motions, isometries). The "multiplication" is the successive application of two operations. As an example, the group tables of the two crystallographic point groups 4 (fourfold 90° rotations, tetragonal) of order 4 (Table 2) and $2_x/m_x 2_y/m_y 2_z/m_z$ (short mmm, orthorhombic) of order 8 (Table 3) are discussed. Table 3 illustrates the various group-subgroup relations within this group: there are seven subgroups of order $N = 4$ and index $[i] = 2$. One of these subgroups, $2_y = m_y$, is displayed in the upper left (4×4) array in Table 3. The full (8×8) group table of $2_x/m_x 2_y/m_y 2_z/m_z$ is obtained from this $2_y/m_y$ subtable by adding any of the operations $2_x, m_x, 2_z$, or m_z . From Table 3, it is easily derived that the seven subgroups of order 4 are $2_x/m_x, 2_y/m_y, 2_z/m_z, 2_x 2_y 2_z, 2_x m_y m_z, m_x 2_y m_z$, and $m_x m_y 2_z$, which are all isomorphic. There are seven further isomorphic subgroups of order 2 and index 4.

Introduction to point groups

Three kinds of three-dimensional groups are fundamental to the study of crystals: point groups, translation groups, and space groups. This article deals with the first type of groups, the point groups. These groups describe and govern the symmetry of finite (nonperiodic, i.e., not containing translations) objects, such as molecules, crystals, flowers, and objects of art, as well as the local symmetries ("site symmetries") of points in a periodic pattern (ornament, wallpaper, crystal structure).

Table 1 Multiplication table of a group $G = \{e, g_2, g_3, g_4, \dots, g_N\}$ of order N .

	e	g_2	g_3	$\dots$	g_N
e	e	g_2	g_3	$\dots$	g_N
g_2	g_2	g_2^2	$g_2 g_3$	$\dots$	$g_2 g_N$
g_3	g_3	$g_3 g_2$	g_3^2	$\dots$	$g_3 g_N$
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$
g_N	g_N	$g_N g_2$	$g_N g_3$	$\dots$	g_N^2

Table 2 Group table (4×4) of the tetragonal crystallographic point group 4: successive 90° rotations forming a cyclic group of order 4, i.e., $4^4 = 1$ (this group is commutative).

	1	4^1	$4^2 = 2$	$4^3 = 4^{-1}$
1	1	4^1	2	4^3
4^1	4^1	2	4^3	1
$4^2 = 2$	2	4^3	1	4^1
$4^3 = 4^{-1}$	4^3	1	4^1	2

There is one subgroup of order $N = 2$ and index $[i] = 2$ with elements $\{1, 2\}$ (180° rotation).

Table 3 Group table (8×8) of the orthorhombic crystallographic point group $2_{\times}/m_x 2_y/m_y 2_z/m_z$ (short *mmm*) of order $N = 8$.

	1	2_y	m_y	$\bar{1}$	$\vdots$	$2_{\times}$	m_x	2_z	m_z
1	1	2_y	m_y	$\bar{1}$	$\vdots$	$2_{\times}$	m_x	2_z	m_z
2_y	2_y	1	$\bar{1}$	m_y	$\vdots$	2_z	m_z	$2_{\times}$	m_x
m_y	m_y	$\bar{1}$	1	2_y	$\vdots$	m_z	2_z	m_x	$2_{\times}$
$\bar{1}$	$\bar{1}$	m_y	2_y	1	$\vdots$	m_x	$2_{\times}$	m_z	2_z
...	...	...	...	...	...	...	...	...	...
$2_{\times}$	$2_{\times}$	2_z	m_z	m_x	1	$\bar{1}$	2_y	m_y	2_z
m_x	m_x	m_z	2_z	$2_{\times}$	$\bar{1}$	1	m_y	2_y	$\bar{1}$
2_z	2_z	$2_{\times}$	m_x	m_z	2_y	m_y	1	$\bar{1}$	2_z
m_z	m_z	m_x	$2_{\times}$	2_z	m_y	2_y	$\bar{1}$	1	2_z

The top left (4×4) array (separated by dotted lines) is the group table of the subgroup $2_y/m_y$ of order $N = 4$ and index $[i] = 2$. The group *mmm* can be obtained from the subgroup $2_y/m_y$ by "extension" of its (4×4) group table by any of the additional operations $2_{\times}$, m_x , 2_z or m_z (here by $2_{\times}$ as the fifth element), each leading to the same supergroup *mmm* of index $[i] = 2$. Both, group and supergroup, are commutative, because all group elements g_i are binary.

In a more subtle fashion, one can distinguish two kinds of point-group symmetries:

1. Symmetry in "vector space": symmetry of a set of vectors, for example, of the face normals of a crystal ("crystal form"), of the translation vectors of a crystal lattice, and of the interatomic vectors of a crystal structure (Patterson vectors). These symmetries are visualized best as vector bushels originating from a common origin.
2. Symmetry in "point space": symmetry of any finite polyhedron, of a molecule, or of an atomic group; symmetry around an arbitrary point in an infinite crystal structure ("site symmetry") or around a lattice node in an infinite point lattice ("lattice point group").

It should be noted that in many textbooks on crystals, two terms are in general use: "point group" as the symmetry of a particular crystal and "crystal class" as the set of all crystals with the same point-group symmetry. Both receive the same symbol. It is of interest that the 32 three-dimensional crystallographic point groups were derived already around 1830.

General and crystallographic point groups

Point groups can be subdivided into crystallographic and noncrystallographic point groups. Both together are called general point groups.

General point groups

A "general point group" is a group of rigid motions (symmetry operations, isometries) which all leave at least one point of space invariant.

This definition leads to infinitely many mono-axial point groups, because it admits infinitely many rotation groups with rotation angles $\varphi = 360^\circ/n$ for all integer values of n . All these rotation groups are of finite order $N = n$. Furthermore, there are some point groups of order $N = \infty$, because they contain rotations (or rotoinversions) of order infinity, that is, rotations with all possible (including arbitrarily small) rotation angles. These rotation groups of infinite order are symbolized as ∞ and ∞/m in Hermann-Mauguin notation and as C_∞ and $C_{\infty h} = C_{\infty i} = S_\infty$ in Schoenflies notation. They appear as symmetry elements of cones, cylinders, circles, and spheres. For details see the "Further reading" section, especially Vol. A of the *International Tables*.

The condition "leave at least one point of space invariant" means that all symmetry elements of the group (axes, planes, and point) intersect at this one point, thus excluding any translations among the symmetry operations. Invariance of more than one point is of course possible, but always leads to infinitely many invariant points. Examples are all "monoaxial" groups n (one rotation axis only), which have an invariant line, and the reflection group m , which has an invariant plane. The intersection of several rotation axes in one point or the presence of a center of symmetry $\bar{1}$, leads to only one invariant point which represents the center of the object.

Crystallographic point groups

A "crystallographic point group" is a group of rigid motions which all leave at least one point of space invariant and, in addition, map a point lattice onto itself ("crystallographic restriction").

As described elsewhere in this encyclopedia, the crystallographic restriction (lattice condition) restricts the permissible rotation angles to multiples of 180° , 120° , 90° , and 60° (two-, three-, four-, and sixfold axes). This reduces the infinitely many point groups to 10 for two dimensions and to 32 for three dimensions. The highest group orders are $N = 12$ for two and $N = 48$ for three dimensions.

Among the 32 three-dimensional crystallographic point groups, there are 11 centrosymmetric groups (so-called Laue groups), which are important in X-ray diffraction, and seven lattice point symmetries (holohedries), defining the seven crystal systems. It should be noted that the 32 three-dimensional crystallographic point groups discussed below can be attributed to 18 isomorphism classes (abstract point groups). A classification of the crystallographic point groups with respect to physical properties is given in Table 5.

Among the three-dimensional noncrystallographic point groups there are the two icosahedral point groups, which contain 6 fivefold, 10 threefold, and 15 twofold rotation axes. They have recently received particular attention due to their occurrence in quasicrystals and fullerenes.

In modern crystallography, point groups in four, five, and six dimensions have been derived and are used for the treatment of incommensurate and quasicrystals. There are 271 point groups in four, 955 in five, and 7104 in six dimensions, with highest orders $N = 1152$, 3840, and 51,840, respectively.

Symbols of the 32 crystallographic point groups

The two systems of symbols for the crystallographic point groups are briefly reviewed here:

1. Schoenflies symbols, first presented in 1891 in Schoenflies' classical book, are based on capital letters for rotation groups C , D , S , T , O with subscripts s , h , v , d for mirror planes in various orientations, and subscript i for an inversion center. The noncrystallographic icosahedral and sphere groups are denoted by letters I_h and K_h (for German "Kugelgruppe").
2. The Hermann-Mauguin or international symbols are based on the "blickrichtungen" (symmetry directions) of the various lattices (holohedries), with specific numbers 2, 3, 4, 6 for symmetry axes, m for a mirror plane, and $\bar{1}$ for an inversion center. The Hermann-Mauguin symbols for the icosahedral and the sphere groups are $2/m\bar{3}5$ (often written as $\bar{5}32/m$) and $2/m\infty$ (often written as $\infty\infty m$).

Symbols and groups orders of the 32 three-dimensional crystallographic point groups, both in Schoenflies and Hermann-Mauguin notation, are illustrated in Fig. 1.

Description of point groups

A formal description of point groups is already given by their group tables, in the section "Brief review of groups" and in Tables 1–3 of this article.

Algebraically, the point groups are usually represented by matrix groups, that is, by the set of (3×3) matrices W of their point group operations (motions, isometries) with determinants $+1$ and -1 or, in a more condensed form, by either the N (contravariant) coordinates x, y, z , of the symmetrically equivalent points, or the N (covariant) Miller indices $\{hkl\}$ of the symmetrically equivalent faces of the "general face form" (crystal form). N is the order of the point group.

Example: point group $2_y/m_y$ (cf. subgroup in Table 3), consisting of $N = 4$ group elements $1, 2_y, m_y, \bar{1}$:

1. coordinates of equivalent general points: x, y, z (1), $-x, y, -z$ (2_y), $x, -y, z$ (m_y), $-x, -y, -z$ ($\bar{1}$);
2. Miller indices of equivalent general faces: (hkl) (1), $(\bar{h}, k, l)$ (2_y), $(h, \bar{k}, l)$ (m_y), $(\bar{h}, \bar{k}, \bar{l})$ ($\bar{1}$).

A complete algebraic representation of the 10 two- and the 32 three-dimensional crystallographic point groups, as well as of the two icosahedral groups is given in Vol. A of the International Tables (cf. "Further reading" section).

Geometrically, a point group is normally represented by means of the stereographic projection of its "framework of symmetry," that is, the spatial assemblage of its symmetry elements (rotation axes, mirror planes, and center of symmetry).

Fig. 1 shows the stereographic projections of the symmetry frameworks of the 32 three-dimensional crystallographic point groups, as well as the two icosahedral groups. The graphical symbols of rotation and rotoinversion axes, mirror planes, and inversion centers are explained elsewhere in this encyclopedia.

The most frequent use of these stereographic projections in mineralogy and crystallography is the characterization of the crystal morphology by the normals of the crystal faces (face poles), leading to the face forms (crystal forms), that is, sets of symmetrically equivalent faces. Each point group (order N) has a "general" face form $\{hkl\}$ with N faces, each one of "face symmetry" 1, and up to six "special" face forms with N/q faces with "face symmetry" >1 of order q , for example, $\{hk0\}$, $\{111\}$, $\{100\}$. Example: the face form cube $\{100\}$ has six faces with "face symmetry" 4 mm (order 8) in point group $4/m\bar{3}2/m$ (order $6 \times 8 = 48$).

Complete listings of all general and special face forms of the crystallographic point groups and the icosahedral groups are presented in Vol. A of the International Tables (see the "Further reading" section).

Triclinic system

Trigonal system

Hexagonal system

Cubic system

Icosahedral point groups (noncrystallographic)

Fig. 1—cont'd

tetragonal holohedry $4mm$ ($N = 8$), for three dimensions (Fig. 2B) the cubic holohedry $4/m\bar{3}2/m$ ($N = 48$) and the hexagonal holohedry $6/m2/m2/m$ ($N = 24$). Their subgroups “mix” on the levels $N = 4$ (Fig. 2A) and $N = 12$ (Fig. 2B), where common subgroups of both branches appear first. Reading the diagrams downward, solid and dashed lines connect a point group G with all its maximal subgroups H . The subgroup index $[i]$ is given by the ratio of the group orders of G and H : $[i] = N(G)/N(H)$. If the diagrams are read upward, the lines connect a point group H with all its minimal supergroups G , with supergroup index $[i] = N(G)/N(H)$. The index $[i]$ is always an integer, according to the theorem of Lagrange.

In the diagrams, solid lines refer to normal subgroups, dashed lines to sets of conjugate subgroups. Two subgroups $\mathcal{H}_1$ and $\mathcal{H}_2$ are conjugate in G , if (at least) one symmetry operation g_j of G exists which maps $\mathcal{H}_1$ onto $\mathcal{H}_2$: $g_j^{-1} \circ \mathcal{H}_1 \circ g_j = \mathcal{H}_2$. Conjugate subgroups are “symmetrically equivalent” in G . If a subgroup H is equivalent only to itself (self-conjugate) and to no other subgroup, H is a normal (invariant) subgroup of G .

Example: the cubic point group $2/m\bar{3}$ (short: $m\bar{3}$) has six maximal subgroups. They are:

- two normal subgroups, one 23 (cubic) of index [2], and one $2/m2/m2/m$ (short: mmm , orthorhombic) of index [3];
- one set of four conjugate subgroups $\bar{3}$ (trigonal) of index [4]. They are symmetrically equivalent (conjugate) under the “lost” twofold rotations of $2/m\bar{3}$.

In three dimensions, [4] is the largest index of a maximal subgroup of a crystallographic point group. In two dimensions, it is [3]. Note that orthorhombic $2/m2/m2/m$ has three normal (nonconjugate) subgroups of the same type, $mm2$, $m2m$, and $2mm$, whereas the cubic point group 23 has four conjugate (symmetrically equivalent) subgroups of type 3.

When a crystal of symmetry G undergoes a (displacive) phase transition to a lower point group symmetry H , it splits into (twin) domains which are related by the lost symmetry operations of G . The number of domain states (orientation states) equals the subgroup index $[i] = N(G)/N(H)$.

Examples

1. Quartz (SiO_2) possesses the point group 32 of order $N = 6$ at room temperature. Upon heating above $T_c = 573^\circ\text{C}$, it transforms into “high-quartz” with point group 622 and order 12. Upon cooling back below T_c , it loses the twofold axis 2 (contained in the hexagonal axis 6) and returns to “low-quartz” with symmetry 32, whereby it splits into domains of $[i] = 2$ orientation states (“Dauphine twin”). This is an example of a nonferroelastic transition and merohedral twinning.
2. Barium titanate (BaTiO_3) (and other perovskite compounds) undergoes, by cooling below 1251°C , a ferroelastic and ferroelectric cubic-to-tetragonal phase transition from point group $4/m\bar{3}2/m$ (order 48) to $4mm$ (order 8) of index $[i] = 6$. This one-step transformation can be rationalized as a succession of two maximal-subgroup steps:
 - (a) Reduction from $4/m\bar{3}2/m$ to $4/m2/m2/m$ (order 16), both centrosymmetric, with subgroup index [3]. This leads to a set of three conjugate tetragonal subgroups with their tetragonal axes oriented along the former three fourfold cube axes as well as to three ferroelastic 90° domain states.
 - (b) Further reduction of each of the three conjugate $4/m2/m2/m$ subgroups to its normal subgroup $4mm$ of index [2], leading to two antiparallel ferroelectric domain states (180° domains).

The total index of both transition steps is $[3] \times [2] = [6]$. As a result, six different “orientation states” (domain states) are generated: three ferroelastic 90° domain states (pseudo-merohedral twins) [due to step (1)], each one being further split into two ferroelectric 180° domain states (merohedral inversion twins) [result of step (2)].

Symmetry of physical properties

Definition of tensor symmetry

Physical properties of crystals are strongly governed by symmetry. This holds in particular for the (nonscalar) anisotropic properties described by tensors, and for nontensorial properties such as cleavage and plasticity for which a comprehensive mathematical treatment does not exist. The components of the tensors describing crystal properties are usually referred to a Cartesian coordinate system, that is, three orthogonal axes X_1, X_2, X_3 with equal unit lengths.

Whereas the anisotropic properties themselves are independent of the choice of the coordinate system, their representation by tensors is not, that is, the tensor components change if the coordinate system is transformed. As a consequence, the symmetry of a physical property can be defined in two alternative, but equivalent ways:

1. a rigid motion (rotation, reflection, and inversion), represented by a unitary matrix W ($\det W = \pm 1$), is applied to the crystal, whereby the coordinate system is kept stationary. All motions, for which the tensor components of the transformed crystal are unchanged, are symmetry operations of the tensor property P ;
2. alternatively, an arbitrary motion W is applied to the coordinate system with the crystal kept stationary. All motions, for which the tensor components are unchanged under the coordinate transformations W , are symmetry operations of the tensor property P . In both cases the rotation matrices are inverse to each other.

As a consequence of this invariance, some of the tensor components are equal or even zero. The number of independent components is decreased when the symmetry of the crystal increases. Thus, an increase of the point-group symmetry from 1 (triclinic) to $4/m\bar{3}2/m$ (cubic) or to the sphere group $\infty\infty m$ (i.e., isotropy) reduces the number of tensor components for symmetrical second-rank tensors from 6 to 1, and for double-symmetrical fourth-rank tensors (e.g., elasticity) from 21 to 3 (cubic) and 2 (isotropy). Even more drastic is this reduction for all tensors of odd rank (such as pyroelectricity and piezoelectricity): all components are zero if an inversion center is present, that is, properties described by odd-rank tensors do not exist in centrosymmetric crystals. This is further elucidated below.

Neumann's principle

A useful group-subgroup relation between physical and crystallographic symmetries is provided by "Neumann's principle" (first stated in 1833). It states that the symmetry of all physical properties of a crystal is higher than (or at least equal to) its crystallographic point-group symmetry, or in the language of groups: the crystallographic symmetry G is a proper or improper subgroup of any physical symmetry $\mathcal{P}$, $G \subseteq \mathcal{P}$. This is illustrated in Table 4 for second-rank tensors which are, as all even-rank tensors, centrosymmetric. Their symmetries can be recognized by their representation surfaces, which are always ellipsoids or hyperboloids. The symmetry of a general ellipsoid or hyperboloid is $2/m\ 2/m\ 2/m$, but it degenerates to cylindrical and spherical symmetries with point groups $\infty/m\ 2/m\ (\infty\ 2/m)$ and $\infty\infty m\ (2/m\ \infty)$ for uniaxial (i.e., tetragonal, trigonal, hexagonal) and cubic crystals. It is obvious that in all cases the crystallographic symmetry is a proper subgroup of the "physical symmetry," except for the orthorhombic holohedry, for which they are identical. Note that all point groups within the same crystal system (e.g., orthorhombic 222 , $mm2$, $2/m2/m2/m$) exhibit the same second-rank tensor symmetry.

In column 5 the terms "biaxial" and "uniaxial" refer to the number of "optical axes", i.e., of circular sections through the index ellipsoid. For uniaxial crystals, the rotation axis of the tensor surface coincides with the main crystallographic symmetry axis. For orthorhombic crystals, the three principal tensor axes and the crystallographic symmetry axes are parallel. For monoclinic crystals, one principal tensor axis is fixed by symmetry; it is parallel to the monoclinic symmetry axis. For triclinic crystals, none of the principal tensor axes is fixed by symmetry, allowing their "orientation dispersion", e.g., with temperature.

The more the physical symmetry approximates the crystallographic symmetry, the higher the rank of its tensor. For example, in cubic crystals tensor properties of second rank are isotropic, whereas fourth rank tensors (e.g., linear elasticity) are not isotropic; they exhibit cubic crystallographic symmetry. For hexagonal crystals, on the other hand, the sixfold axis is still a continuous rotation axis also for fourth rank tensors.

Tensors of odd rank

Physical properties represented by odd-rank tensors are of particular importance for technological applications. Pyroelectricity and piezoelectricity under hydrostatic pressure are properties of first rank, represented by maximally three independent coefficients (i.e., by a vector). Important third-rank properties are piezoelectricity (under general stress), optical second-harmonic generation, and linear electrooptics. Odd-rank tensors are subject to strong constraints by symmetry, in particular by an inversion center which renders all tensor components zero, that is, properties of odd rank do not exist in centrosymmetric crystals.

Pyroelectricity and ferroelectricity

Pyroelectricity originates from a permanent electric dipole moment of the unit cell of the crystal structure or, in macroscopic terms, from an intrinsic ("spontaneous") electrical polarization. This polarization is changed by heating and cooling, thus giving rise to electric charges on certain crystal faces.

In a crystal, a spontaneous polarization can be present only along a polar direction which has no symmetrically equivalent directions. (In the literature, the condition for the occurrence of pyroelectricity is frequently expressed as "a unique (or singular) polar axis." This term, however, is misleading for point groups m and 1 .) Such polar directions occur in the following

Table 4 Symmetry of second-rank polar tensor properties and optical birefringence (refractive-index ellipsoids) in the seven crystal systems.

Crystal system	Holohedry	Type of ellipsoid or hyperboloid	Symmetry of tensor property	Optical birefringence (index ellipsoid)
Triclinic	$\bar{1}$	General	$2/m\ 2/m\ 2/m$	Biaxial
Monoclinic	$2/m$	General	$2/m\ 2/m\ 2/m$	Biaxial
Orthorhombic	$2/m\ 2/m\ 2/m$	General	$2/m\ 2/m\ 2/m$	Biaxial
Tetragonal	$4/m\ 2/m\ 2/m$	Rotational	$N/m\ 2/m$	Uniaxial
Trigonal	$\bar{3}\ 2/m$	Rotational	$N/m\ 2/m$	Uniaxial
Hexagonal	$6/m\ 2/m\ 2/m$	Rotational	$N/m\ 2/m$	Uniaxial
Cubic	$4/m\ \bar{3}\ 2/m$	Spherical	$\infty\infty m\ (2/m\ \infty)$	Isotropic

Table 5 The 21 noncentrosymmetric crystallographic point groups (crystal classes) and the occurrence (+) of specific crystal properties.

Crystal system	Noncentrosymmetric point group	First-rank tensor (e.g., pyroelectricity)	Third-rank tensor (e.g., piezoelectricity)	Enantiomorphism	Optical activity (opt. gyration)

The number of nonzero independent tensor components is given in parentheses. For comparison, the noncentrosymmetric icosahedral and the sphere group (isotropy) are added. For first-rank tensors the direction [*uvw*] of the property vector is given. There are 10 pyroelectric, 20 piezoelectric, 11 enantiomorphic and 15 optically active crystal classes.

^aUnique axis *b*.

^bHexagonal axis.

10 (“pyroelectric”) point groups: 6, 4, 3, 2, 1, and their combination with a “parallel” mirror plane: 6 *mm*, 4 *mm*, 3 *m*, *mm2*, *m* (Table 5). In point groups with a rotation axis, the electric polarization (“pyroelectric vector” *p*) is fixed parallel to this polar axis. For point group *m*, the pyroelectric vector *p* is oriented parallel to the mirror plane, and for point group 1 any direction of *p* is possible.

A polar crystal is ferroelectric if the direction of the spontaneous polarization can be reversed (“switched”) by an electric field, leading to a hysteresis behavior. Thus, ferroelectricity can only occur in the 10 pyroelectric point groups.

Piezoelectricity

Among the third-rank property tensors, piezoelectricity and its converse effect, the piezoelectric strain (“linear electrostriction”), are the most important properties for technological applications (pressure sensors, resonators, etc.). Well-known examples are single crystals of quartz (SiO₂) and textured (“poled”) ceramics of barium titanate (BaTiO₃). Of similar significance are, nowadays, the third-rank tensors of optical second-harmonic generation (for optical frequency doubling, for example, potassium dihydrogen phosphate, KDP) and of linear electrooptics (Pockels effect) (for light modulation, e.g., KDP).

Third-rank properties occur in all noncentrosymmetric crystal classes, except for the cubic class 432, where the combination of three perpendicular equivalent fourfold axes causes all tensor components to vanish. The combination of three equivalent twofold axes, present in the two cubic classes 23 and $\bar{4}3m$, however, still admits one independent nonzero component. The tensor is the same for both classes and exhibits the symmetry $\bar{4}3m$ (Table 5).

Piezoelectricity under hydrostatic pressure is possible only in the 10 pyroelectric crystal classes (see Table 5). An example for use of this effect for pressure sensors (e.g., formerly for submarines) is provided by Li₂SO₄ · H₂O (point group 2) single crystals.

Enantiomorphism and optical activity (optical gyration)

Enantiomorphism is a qualitative property stating that an object (molecule, crystal) may have a right- and a left-handed (“mirror image”) form or structure. This feature requires the absence of any “hand-changing” operation ($\det W = -1$), such as a reflection or roto-inversion (including the inversion 1). Thus, only the 11 non-centrosymmetric crystal classes containing only proper rotations

($\det W = +1$) allow enantiomorphism (Table 5). Enantiomorphism, of course, is also possible in noncrystallographic symmetry groups without mirror planes and rotoinversion axes.

Optical gyration is described by a second-rank tensor, but in contrast to the polar tensors of second rank shown in Table 4, it has an axial character, that is, it exhibits the features of a screw. Thus, the components of the axial gyration tensor change their signs if the handedness of the coordinate system is changed from right to left, and vice versa. Consequently, the invariance condition for tensor components g_{ij} under symmetry transformations, as described in the section “Definition of tensor symmetry” for polar tensors, has to be modified as follows: for all “hand-changing” symmetry operations W (i.e., $\det W = -1$), the transformed components $\tilde{g}_{ij}$ must equal their negative counterparts: $\tilde{g}_{ij} = (-1)g_{ij}$. From this, it follows directly that optical activity is forbidden in all centro-symmetric crystal classes. For proper rotations which preserve the handedness, a change of sign does not occur. Thus, all symmetry groups allowing enantiomorphism also permit optical activity. Crystals belonging to one of the enantiomorphic crystal classes may occur in two forms, either left- or right-handed, which exhibit opposite senses of rotation of the plane of polarization. A well-known example is provided by quartz SiO_2 (enantiomorphic crystal class 32), which crystallizes in a right- and a left-hand form with opposite senses of optical activity.

In addition to the 11 enantiomorphic crystal classes, there are four nonenantiomorphic classes exhibiting optical activity: m , $mm2$, $\bar{4}$, $\bar{4}2m$. In these cases, optical activity does not occur for all directions of light propagation, viz. not those parallel to the $\bar{4}$ axis and parallel or normal to the mirror plane m . All other propagation directions exhibit activity, whereby directions symmetrical with respect to $\bar{4}$ and m show opposite rotation senses. Thus, the four symmetry groups above show both (right and left) rotation senses in one and the same crystal.

The optical activity is isotropic in cubic crystals, as it is in optically active liquids (e.g., in solutions of dextro- or levo-sugar). In this case, the symmetry of the optical activity is described by the noncentro-symmetric sphere group $\infty \infty (2 \infty)$. Geometrically, this symmetry group can be represented by a (right- or left-hand) rotating sphere or by a sphere which is densely covered with either right- or left-hand swirls.

Curie's principle

Until now the symmetry group G_P of physical properties of a “free” macroscopic crystal C with point group G_C was discussed. Now, the symmetry G_{CF} of a crystal C which is subject to an external influence F , for example, to an electric field, to uniaxial stress, to temperature changes, etc., is considered. For this treatment, point-group symmetries G_F of the external influences (Curie groups) are defined as follows:

1. Homogeneous electric field E : ∞m (polar continuous rotation axis with “parallel” mirror planes, that is, symmetry of a stationary cone). Note that a rotating cone (left- or right-hand) represents geometrically the polar enantiomorphous group ∞ ; a stationary cone represents the polar group ∞m with “vertical” mirror planes.
2. Homogeneous magnetic field H : ∞/m (symmetry of a rotating cylinder).
3. Uniaxial stress σ_{ii} : $\infty/m \ 2/m$ (symmetry of a stationary centrosymmetric cylinder).
4. Temperature change ΔT or hydrostatic pressure $-\sigma$ (scalars): $\infty \infty m$ (symmetry of a stationary centrosymmetric sphere).
5. Shear stress σ_{ii} : $2/m \ 2/m \ 2/m$ (orthorhombic).

According to Curie's principle of 1894, the point-group symmetry G_{CF} of the crystal under the external field is the intersection symmetry of the symmetry G_C of the crystal without field and the symmetry G_F of the field without crystal: $G_{CF} = G_C \cap G_F$; that is, G_{CF} is a (proper or improper) subgroup of both groups G_C and G_F .

As examples, consider the effect of an electric field ($G_F = \infty m$) and a uniaxial stress ($G_F = \infty/m \ 2/m$) along one of the (four) threefold rotoinversion axes 3 of cubic crystals with point groups $G_C = 2/m\bar{3}$ and $G_C = 4/m\bar{3} \ 2/m$

- Electric field parallel $[1 \ 1 \ 1]$:

$$2/m\bar{3} \cap \infty m :$$

$$G_{CF} = 3 \text{ along } [1 \ 1 \ 1] \\ (\text{pyroelectric; optically active})$$

$$4/m\bar{3} \ 2/m \cap \infty m :$$

$$G_{CF} = 3m \text{ along } [1 \ 1 \ 1] \\ (\text{pyroelectric})$$

- Uniaxial stress parallel $[1\ 1\ 1]$:

$$2/m\bar{3} \cap \infty/m\ 2/m :$$

$$\mathcal{G}_{CF} = \bar{3} \text{ along } [1\ 1\ 1]$$

$$4/m\bar{3}\ 2/m \cap \infty/m\ 2/m :$$

$$\mathcal{G}_{CF} = \bar{3}2/m \text{ along } [1\ 1\ 1]$$

Note that, in contrast to uniaxial stress, the electric field destroys centrosymmetry, leading to pyroelectricity and even optical gyration. The polarity and the gyration sense are reversed upon reversal of the electric field. If the electric field and the uniaxial stress were applied to an arbitrary (nonsymmetry) direction of the above cubic crystals, point groups 1 and $\bar{1}$ would result in the two cases.

If a scalar influence, which is represented by the centrosymmetric sphere group G_E , for example, a temperature change ΔT , is applied to a crystal, its symmetry is not changed, $G_{CF} = G_C$, provided that no phase transition is induced. For further reading on the symmetry of physical properties, refer to the “Further reading” section.

Nomenclature

a, b, c	lattice basis vectors
$a^* b^* c^*$	reciprocal lattice basis vectors
A	translation subgroup of a space group
$D(R)$	matrix representation
$\exp(-ik \cdot r)U(r)$	Bloch form of a wave function
$E(3)$	Euclidean group
$F(k)$	structure factor
G	space group
K	point group
n	lattice translation vector
$O(3)$	orthogonal group in three dimensions
r_j	position of an atom in the unit cell
R	orthogonal transformation
$\{R t\}$	space group element
T_g	linear operator for group element g :
$\hat{\rho}(k)$	Fourier component of $\rho(r)$
$\rho(r)$	density function
ψ_i	basis of a state space
$\psi(r)$	wave function

Introduction

For the description or the study of properties of physical systems, symmetry is of paramount importance. The symmetry groups of crystals are the so-called space groups. Other symmetry operations, such as time reversal, are sometimes also relevant, but the most important operations are the elements of the space groups. Space group symmetry is a generalization of the property that crystals are, usually, periodic in three dimensions. This article deals with the periodicity, the other symmetry operations of crystals, the classification of the space groups, and, what is of greater relevance for the physical properties, their representations.

Lattice Periodicity

Ideally, the most common crystals consist of a periodic array of identical building blocks repeated in all three directions. There are other types of crystals also, but a discussion of these will be taken up at the end of this section. Real crystals always have shortcomings in their periodic order; they are finite, which implies that there is a limit to the periodicity. Repetition means that one may go from one block into another by a translation. Such a translation is given by a vector n . All vectors of the translations

form a lattice. That means there are three fundamental translations, with vectors $\mathbf{a}$, $\mathbf{b}$, and $\mathbf{c}$, such that each lattice translation $\mathbf{n}$ is a linear combination of these three with integer coefficients, and each such combination transforms a building block into another:

$$\mathbf{n} = n_1\mathbf{a} + n_2\mathbf{b} + n_3\mathbf{c}, \text{ with integers } n_1, n_2, n_3 \quad [1]$$

The building blocks do not have an overlap, and there are no gaps between them. Each building block consists of an arrangement of atoms or molecules. It is called a unit cell. The whole structure then remains the same if it is shifted by any of the translations of the lattice. Suppose that there are N atoms in the building block at positions $\mathbf{r}_1, \dots, \mathbf{r}_N$. Then the position of an arbitrary atom of the crystal is given by the expression

$$\mathbf{r}_{nj} = \mathbf{r}_j + n_1\mathbf{a} + n_2\mathbf{b} + n_3\mathbf{c} \quad [2]$$

for specific values of j , n_1 , n_2 , and n_3 . The vectors $\mathbf{r}_j$ may be chosen inside the unit cell. The vectors $\mathbf{a}$, $\mathbf{b}$, and $\mathbf{c}$ are the basis vectors.

Because the building blocks are repeated in all directions, the three fundamental vectors are independent, which also means that every point in space can be reached from a fixed point by a linear combination, not necessarily with integer coefficients. In general, the coefficients are real numbers. In particular, the position of an arbitrary atom with respect to a chosen origin can be written as

$$\mathbf{r}_{nj} = (n_1 + \xi_1)\mathbf{a} + (n_2 + \xi_2)\mathbf{b} + (n_3 + \xi_3)\mathbf{c} \quad [3]$$

Here $(n_1 + \xi_1)$, etc., are real numbers. For example, for CsCl, the three basis vectors are in Cartesian coordinates $(a, 0, 0)$, $(0, a, 0)$, and $(0, 0, a)$. There is a Cs atom at $\mathbf{r}_1 = (0, 0, 0)$ and a Cl atom at $\mathbf{r}_2 = (a/2, a/2, a/2)$. With respect to the lattice basis, the Cl coordinates are $\xi_1 = \xi_2 = \xi_3 = 1/2$. The unit cell is a cube.

Distance-Preserving Transformations

Physical laws remain the same if positions are transformed into newer positions with the same distances. Therefore, such distance-preserving transformations are important for physics. Among them are translations, where all positions are shifted by the same translation vector. In addition, rotations around an arbitrary point and the full reflection of all points through an arbitrary point leave the distances invariant. Let O be an arbitrary point in space. Then the orthogonal group consists of all rotations leaving this point invariant and all products of such a rotation with the reflection through O . The group of three-dimensional orthogonal transformations is denoted by $O(3)_O$. Choosing O as origin and a basis of space consisting of three basis vectors $\mathbf{e}_1$, $\mathbf{e}_2$, $\mathbf{e}_3$, an orthogonal transformation R corresponds to a matrix via

$$R\mathbf{e}_i = \sum_{j=1}^3 R_{ji}\mathbf{e}_j \quad (i = 1, 2, 3) \quad [4]$$

For a special choice of the basis, namely, with three mutually perpendicular vectors of the same length, the matrices satisfy $\sum_j R_{ij}R_{kj} = \delta_{ik}$ or $RR^T = E$, where T indicates the transpose, and E the unit matrix. Such matrices are called orthogonal. Their determinant is either $+1$ (for rotations) or -1 . If one chooses another origin, the orthogonal group around that point gives the same group of matrices, which can then be indicated by $O(3)$.

All distance-preserving transformations can be obtained as a combination of a translation and an orthogonal transformation around an origin O . The effect on a point $\mathbf{r}$ of an orthogonal transformation R together with a translation $\mathbf{t}$ is

$$\{R|\mathbf{t}\}\mathbf{r} = R\mathbf{r} + \mathbf{t} \quad [5]$$

All these transformations again form a group, the Euclidean group $E(3)$. Its elements are called Euclidean transformations. The product of two such transformations then is the subsequent execution of the two:

$$\begin{aligned} \{R_1|\mathbf{t}_1\}\{R_2|\mathbf{t}_2\}\mathbf{r} &= \{R_1|\mathbf{t}_1\}(R_2\mathbf{r} + \mathbf{t}_2) \\ &= R_1R_2\mathbf{r} + R_1\mathbf{t}_2 + \mathbf{t}_1 \end{aligned} \quad [6]$$

from which it follows that

$$\{R_1|\mathbf{t}_1\}\{R_2|\mathbf{t}_2\} = \{R_1R_2|\mathbf{t}_1 + R_1\mathbf{t}_2\} \quad [7]$$

In particular, $\{R|\mathbf{t}\} = \{E|\mathbf{t}\}\{R|\mathbf{0}\}$ and $\{R|\mathbf{t}\}^{-1} = \{R^{-1}|\mathbf{-R}^{-1}\mathbf{t}\}$.

A rotation R from $O(3)_O$ leaves the point O invariant. A translation $\mathbf{u}$ transfers O to $O+\mathbf{u}$ and this point is left invariant by $\{E|\mathbf{u}\}\{R|\mathbf{0}\}\{E|\mathbf{-u}\}$. This means that, the product $\{R|\mathbf{u}-R\mathbf{u}\}$ belongs to the orthogonal group $O(3)_{O+\mathbf{u}}$. In other words, the translation part $\mathbf{t}$ of a space group element $\{R|\mathbf{t}\}$ may be changed by an origin shift $\mathbf{u}$ according to

$$\mathbf{t} = \mathbf{t} + (E - R)\mathbf{u} \quad [8]$$

The combination of a translation and a rotation around O is then the same as a combination of another translation and a rotation around $O+\mathbf{u}$ (see Figure 1).

There is a simple matrix formulation for the action of a Euclidean transformation on a point $\mathbf{r}$ with coordinates x , y , and z :

$$\{R|\mathbf{t}\} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} = \begin{pmatrix} R_{11} & R_{12} & R_{13} & t_1 \\ R_{21} & R_{22} & R_{23} & t_2 \\ R_{31} & R_{32} & R_{33} & t_3 \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \quad [9]$$

Figure 1 The 90° rotation around A brings a to b, a 90° rotation around B plus a translation brings a via c to b.

Space Groups, Plane Groups, Higher Dimensions

A collection of atoms which is invariant under the translations of a three-dimensional lattice is, in general, invariant under still more Euclidean transformations. A space group is a group of Euclidean transformations that has a translation subgroup as a lattice group, with three linearly independent basis vectors. If $\{E|a\}$ is a translation from the translation subgroup, and $\{R|t\}$ an arbitrary element of the space group, then the following relation holds:

$$\{R|t\}\{E|a\}\{R|t\}^{-1} = \{E|Ra\} \quad [10]$$

The first consequence is that the translation subgroup is an invariant subgroup. (A subgroup A of a group G is invariant if, for each element a of A and each g from G , the element gag^{-1} is an element of A .) Because $\{E|Ra\}$ is a translation, and therefore an element of the translation subgroup, Ra belongs to the lattice. Consequently, the lattice is invariant under R , and because all R 's form a subgroup of $O(3)$, this is a crystallographic point group, one of the 32 point groups. The Euclidean transformations leaving the CsCl structure invariant are the 48 elements of the cubic point group, combined with the lattice translations of the cubic lattice.

A plane group is a subgroup of the Euclidean group in two dimensions having as translation subgroup a two-dimensional lattice group. The elements R now form one of the 10 two-dimensional crystallographic point groups. The generalization to space groups in arbitrary dimensions then is straightforward. Such a group in arbitrary dimensions (including two) is also called a space group.

The Structure of a Space Group

The translation subgroup A of a space group G is invariant. (It is also called a normal subgroup.) The orthogonal transformations R appearing in the elements $\{R|t\}$ form a three-dimensional crystallographic point group K . All the elements of K can now be numbered: $R_1=E, R_2, \dots, R_N$. All elements $\{R_i|t\}$ in G form a set S_i for fixed i . One can multiply two such sets: the product $S_i S_j$ is the set S_k if $R_i R_j = R_k$. In this way, the sets S_i form a group, which is in fact identical to the group of all elements R_i , that is, the point group K . The group of sets S_i is called the factor group, and it is identical to (more precisely isomorphic to) the point group K . So, the space group G has an invariant subgroup A and the factor group G/A is isomorphic to the point group K .

From each set S_i , one may choose an element $\{R_i|t_i\}$. Then, every other element from S_i may be written as the product of the representative $\{R_i|t_i\}$ and a lattice translation $\{E|a\}$. Of course, one could have chosen another representative element $\{R_i|t'_i\}$. Then the two translations t_i and t'_i differ by a translation a from the lattice. The translations t_i are not necessarily lattice vectors, and they are determined by R_i only up to a lattice vector. If the representatives can be chosen such that their translation part is zero, that is, when all translations t_i are lattice vectors, the group has a simple structure: each element is a product of an element of the translation subgroup and an element of the point group. Then the space group is called symmorphic.

Consider as examples the plane groups of the two-dimensional structures for which the unit cell is given in Figure 2. The unit cells are rectangles, the lattices have bases vectors $(a, 0)$ and $(0, b)$. The example of Figure 2a has two different atoms in $(0,0)$ and $(1/2, 1/2)$. The point group symmetry of the lattice consists of the identity E , the two mirrors m_x and m_y , and the inversion $-E$. All four elements transform the position of an atom to a position that is related to the original position by a lattice vector. Thus, the plane group has a point group $(2mm)$ with four elements. The example of Figure 2b has one molecule at the position $(0,0)$. There are only two point group elements leaving the molecule invariant, and the point group is 2 with elements E and $-E$, although the

Figure 2 Three unit cells for the space groups (a) pmm , and (b) $p2$, (c) pgg .

lattice is the same. In example (c), there are molecules at $(0, 0)$ and $(1/2, 1/2)$. The subgroup leaving each molecule invariant has two elements: $\pm E$. The transformation m_x does not leave a molecule invariant, but the Euclidean transformation $\{m_x|(1/2, 1/2)\}$ does. The space group elements are the elements of the translation subgroup A and the cosets $\{-E|0\}A$, $\{m_x|(1/2, 1/2)\}A$, and $\{m_y|(1/2, 1/2)\}A$. The point group is again $2mm$.

Space Group Elements

Each element of a space group is a product of an orthogonal transformation (an element of the point group K) and a translation t , the latter not always a lattice translation. The translations t_i form a vector system for the space group. The translations satisfy

$$\begin{aligned} t_i + R_i t_j &= t_k \quad \text{up to a lattice vector } a \\ \text{if } R_i R_j &= R_k \end{aligned} \quad [11]$$

The translations t_i , however, depend on the choice of the origin. According to eqn [8] they change to $t_i + (E - R_i)u$, if the origin is shifted by a translation u . This makes it necessary to review the concept of a symmorphic space group. A space group is called symmorphic if there is an origin such that all representatives $\{R_i|t_i\}$ may be chosen with $t_i=0$. Then each element of G is the product of a point group element and a lattice translation. If the group is not symmorphic, then it is called nonsymmorphic.

A three-dimensional rotation has an axis and a rotation angle. If one chooses an orthonormal coordinate system and the rotation angle along the z -axis, then the rotation is given by a matrix

$$\begin{pmatrix} \cos \varphi & -\sin \varphi & 0 \\ \sin \varphi & \cos \varphi & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

When an orthogonal transformation has a determinant equal to -1 , it has the same form but with an overall minus sign. Consider the case that the orthogonal transformation is combined with a translation t with coordinates a , b , and c in the same reference system. By a shift of origin over the vector u with components x , y , and z , the translation is transformed into the translation $t + (1 - R)u$, with components

$$a + x(1 - \cos \varphi) + y \sin \varphi, b - x \sin \varphi + y(1 - \cos \varphi), c$$

By a proper choice of u , the first two components can be eliminated, but not the third. It is the case of a screw axis, a rotation combined with a translation along the rotation axis. If the rotation is over an angle $\varphi = 2\pi m/n$, with $n=2, 3, 4$, or 6 , the translation is always $1/n$ of a lattice vector. When the determinant is -1 , the origin can always be shifted such that the translation vanishes, except for the case $n=2$. Then the orthogonal transformation is

$$\begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}$$

and the first two components cannot be changed. It is a mirror operation with a translation in the mirror plane, and is called a glide operation. The plane of the mirror is the glide plane (Figure 3).

In two dimensions, the only plane group elements with intrinsic nonzero translation components are glide operations. For a rotation with a translation, the latter can always be eliminated by a shift of the origin.

Classification

Because the orientation and the lattice constants may vary continuously, the number of space groups is infinite. However, there is good reason to identify space groups under certain conditions, for example, if they are just different orientations of the same group

Figure 3 A two-dimensional pattern with pgm symmetry: rectangular lattice, horizontal mirrors, and vertical glides.

in space. In principle, which groups may be identified depends on the physics of the problem one wants to study by symmetry. Space groups are subgroups of the inhomogeneous affine group as well, the group of pairs of nonsingular linear transformations and translations. If a group G_1 may be transformed into group G_2 by a change of origin (translation) and a linear transformation of the lattice (homogeneous affine transformation), the two may be identified, or in other words considered as equivalent, because the choice of origin and basis does not change the physics. This is a definition inspired by physics. In mathematical language, the two groups are conjugated subgroups of the inhomogeneous affine group. This means that the groups G_1 and G_2 are considered to be equivalent if there is a nonsingular linear transformation S and a translation $\{E|t\}$ such that

$$G_1 = \{S|t\}G_2\{S|t\}^{-1} \quad [12]$$

With this relation, there are 219 equivalence classes of three-dimensional space groups. If the handedness of the basis is relevant, for instance, in the case of helical structures, there is a finer definition, which calls the groups equivalent if the conjugation is by an element $\{S|t\}$ such that $\det(S) > 0$. Then there are 230 equivalence classes of space groups in three dimensions. With both definitions, there are 17 different plane groups in two dimensions. A theorem by Bieberbach states that conjugation in the affine group is equivalent to isomorphism.

The space groups can also be grouped into larger classes. A coarser classification uses arithmetic equivalence. Choosing an origin and a lattice basis, the point group K of a space group corresponds to a group of integer matrices $D_1(K)$. After a basis transformation, corresponding to an integer nonsingular matrix S , the same group is represented by an integer matrix group $D_2(K) = SD_1(K)S^{-1}$. Two such groups are called arithmetically equivalent. Then a space group determines an arithmetic crystal class. If one drops the condition that the conjugation matrix S has integer entries and allows real matrices, two groups conjugated by S are said to be geometrically equivalent. Arithmetic equivalence implies geometric equivalence. Space groups may be grouped into affine equivalence classes, and further into arithmetic and geometric crystal classes. In three dimensions, there are 219 affine classes, 73 arithmetic classes, and 32 geometric classes. The latter two classifications can, of course, be used for point groups as well. For each arithmetic class there is exactly one symmorphic space group. Finally, there are seven systems (triclinic, monoclinic, orthorhombic, tetragonal, rhombohedral, hexagonal, and cubic) and six families (each three-dimensional system is a family, except the rhombohedral and hexagonal, which belong to the same family). The reader is referred to more specialized works on crystallography for a definition.

Notation

Because the full explanation of the notation and nomenclature for crystallographic groups requires much more space, only a brief discussion is presented here. There are two systems, the Hermann–Mauguin symbols, recommended by the International Union for Crystallography (IUCr), and the Schoenflies symbols. The latter are based on the symbols for the 32 point groups arranged in geometric classes. For each class there is a numbering of the corresponding space groups. An example is C_2^2 with point group C_2 consisting of an identity and a two-fold rotation. It is the second group with this point group. The Hermann–Mauguin symbols tend to have more information. They are based on the IUCr symbols for point groups. A second ingredient are the lattices. Lattices are considered to be equivalent if the point groups that leave them invariant (which on a lattice basis may be given by groups of integer matrices) may be represented by a change of lattice basis by the same groups of matrices. These classes are the Bravais classes. In three dimensions, there are 14 Bravais classes (Table 1). For lattices with the same point group symmetry, there is a common conventional basis on which the point group elements are simple, but one needs additional lattice vectors. For example, there are three Bravais classes for which the symmetry is the symmetry group of the cube, with 48 elements. The lattices of one Bravais class have a basis with three mutually perpendicular basis vectors of the same lengths. For the other two, the face-centered cubic (f.c.c.) and body-centered cubic (b.c.c.), there is a sublattice of this kind, but not all lattice vectors belong to that. One needs additional vectors to obtain all the lattice translations: $(0, 1/2, 1/2)$, $(1/2, 0, 1/2)$, and $(1/2, 1/2, 0)$ for f.c.c. and $(1/2, 1/2, 1/2)$ for b.c.c. (Figure 4). These additional vectors are given by capital letters in three dimensions, and lower case letters in two dimensions.

Table 1 The 14 Bravais classes in three dimensions and their maximal symmorphic space groups

System	Centering translations	Maximal symmorphic space group	Basis
Triclinic	None	$P -1$	No relations
Monoclinic	None	$P2/m$	$a.c=b.c=0$
	$(1/2, 0, 1/2)$	$B2/m$	
Orthorhombic	None	$Pmmm$	Three axes perpendicular
	$(1/2, 1/2, 1/2)$	$Immm$	
	$(0, 1/2, 1/2), (1/2, 0, 1/2), (1/2, 1/2, 0)$	$Fmmm$	
	$(1/2, 1/2, 0)$	$Cmmm$	
Tetragonal	None	$P4/mmm$	Three axes perpendicular
	$(1/2, 1/2, 1/2)$	$I4/mmm$	$ a = b $
Rhombohedral	None	$R -3m$	$ a = b = c $
			$\angle(a, b) = \angle(b, c) = \angle(c, a)$
Hexagonal	None	$P6/mmm$	$ a = b , c \perp a, c \perp b$
			$\angle(a, b) = 2\pi/3$
Cubic	None	$Pm -3m$	All basis vectors mutually perpendicular and equal in length
	$(0, 1/2, 1/2), (1/2, 0, 1/2), (1/2, 1/2, 0)$	$Fm -3m$	
	$(1/2, 1/2, 1/2)$	$Im -3m$	

Figure 4 Unit cells for lattices from each of the three cubic Bravais classes. (a) Primitive, (b) b.c.c. with additional basis vector $(1/2, 1/2, 1/2)$, and (c) f.c.c. with additional $(0, 1/2, 1/2)$, $(1/2, 0, 1/2)$, and $(1/2, 1/2, 0)$.

The symbols of the symmetry groups of the three cubic lattices are $Pm-3m$, $Fm-3m$, and $Im-3m$. These are the Hermann–Mauguin symbols for the space groups of the primitive cubic, f.c.c., and b.c.c. lattices, respectively. For each of the 73 arithmetic crystal classes, and thus for all symmorphic space groups there is such a symbol, consisting of the symbol for the point group preceded by a letter indicating the additional lattice vectors (the centering).

Finally, for nonsymmorphic space groups, the nonlattice translations for the elements appearing in the symbol for the symmorphic space group are indicated by either a change of the letter or by a subindex. The symbol for a symmorphic space group with point group m may be Pm . If the mirror m becomes a glide with nonlattice translation in the third direction, the symbol is Pc . The symbol $P2$ gives a symmorphic space group with point group 2, $P2_1$ indicates a nonsymmorphic group with a screw axis. All space groups, their symbols and their elements can be found in the *International Tables for Crystallography*, vol. A.

Reciprocal Lattice, Invariant Functions, Extinction Rules

A function that is invariant under translations has special properties for its Fourier transform. Suppose $\rho(\mathbf{r})$ is such a function (e.g., a density function of a crystal). It has the property that $\rho(\mathbf{r})$ and $\rho(\mathbf{r}+\mathbf{a})$ are equal for every translation $\mathbf{a}$ from the lattice. Writing down the Fourier decomposition yields

$$\begin{aligned}\rho(\mathbf{r}) &= \int \hat{\rho}(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{r}) d\mathbf{k} \\ \rho(\mathbf{r} + \mathbf{a}) &= \int \hat{\rho}(\mathbf{k}) \exp(i\mathbf{k} \cdot (\mathbf{r} + \mathbf{a})) d\mathbf{k}\end{aligned}\quad [13]$$

from which it follows that $\mathbf{k} \cdot \mathbf{a} = 0 \pmod{2\pi}$ for each translation vector $\mathbf{a}$. Therefore, for each wave vector $\mathbf{k}$ occurring in the Fourier expansion, one has this relation. All vectors $\mathbf{k}$ satisfying this relation form a lattice, as is easily checked. This lattice is called the reciprocal lattice for the so-called direct lattice of the vectors $\mathbf{a}$.

If $\mathbf{a}$, $\mathbf{b}$, and $\mathbf{c}$ span the direct lattice, a basis for the reciprocal lattice is given by $\mathbf{a}^*$, $\mathbf{b}^*$, $\mathbf{c}^*$ defined by

$$\mathbf{a}^* = 2\pi(\mathbf{b} \times \mathbf{c})/V, \mathbf{b}^* = 2\pi(\mathbf{c} \times \mathbf{a})/V, \mathbf{c}^* = 2\pi(\mathbf{a} \times \mathbf{b})/V \quad [14]$$

where $V = \mathbf{a} \cdot (\mathbf{b} \times \mathbf{c})$ is the volume of the unit cell. Then the Fourier decomposition is

$$\rho(\mathbf{r}) = \sum_{\mathbf{k} \in \Lambda^*} \hat{\rho}(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{r}) \quad [15]$$

where Λ^* is the reciprocal lattice. Each vector of the reciprocal lattice can be expressed in terms of the basis of the lattice

$$\mathbf{k} = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^* \in \Lambda^* \quad [16]$$

The reciprocal lattice is left invariant by the point group K as well.

Apart from translations, a lattice periodic function is generally left invariant by other distance-preserving transformations as well. Suppose $g = \{R|\mathbf{t}\}$ is an element of the space group that leaves a function $\rho(\mathbf{r})$ invariant. This means that $\rho(\mathbf{r})$ and $\rho(g^{-1}\mathbf{r})$ are the same (the exponent -1 is just for convenience). Then one has the relation

$$\rho(\mathbf{r}) = \rho(\{R|\mathbf{t}\}^{-1}\mathbf{r}) \quad [17]$$

For the Fourier components $\hat{\rho}(\mathbf{k})$, this implies

$$\hat{\rho}(\mathbf{k}) = \hat{\rho}(R\mathbf{k}) \exp(iR\mathbf{k} \cdot \mathbf{t}) \quad [18]$$

This is a very interesting formula. It is known that the wave vectors occurring in the Fourier decomposition belong to the reciprocal lattice. Now, consider a reciprocal lattice vector $\mathbf{k}$ that is invariant under orthogonal transformation R . Then the expression becomes

$\rho(\mathbf{k}) = \rho(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{t})$. This is only possible if $\rho(\mathbf{k}) = 0$ or if $\mathbf{k} \cdot \mathbf{t} = 0 \pmod{2\pi}$. If $\mathbf{t}$ is a translation from the lattice, this relation is trivially fulfilled. But if there is a $\mathbf{t}$ such that the second relation is not satisfied, this means that the corresponding Fourier component $\hat{\rho}(\mathbf{k})$ vanishes. This is an extinction rule.

An important example is the diffraction intensity. A crystal diffracts and the diffraction pattern consists of sharp Bragg peaks at the positions $\mathbf{k}$. The intensity of the peaks is given by the square of the absolute value of the static structure factor:

$$I(\mathbf{k}) = |F(\mathbf{k})|^2 = \left| \frac{1}{N} \sum_{j=1}^N \exp(i\mathbf{k} \cdot \mathbf{r}_j) \right|^2 \quad [19]$$

Here j runs over the N particles in the unit cell. It is the Fourier transform of the autocorrelation function, which is invariant under space group elements. Hence, the positions of the Bragg peaks are on the reciprocal lattice, and the extinction rules apply: the intensity is zero at $\mathbf{k}$ if there is a space group element $\{R|\mathbf{t}\}$ with $R\mathbf{k} = \mathbf{k}$ and $\mathbf{k} \cdot \mathbf{t} \neq 0 \pmod{2\pi}$. Additionally, one has for arbitrary $\mathbf{k}$ that $I(R\mathbf{k}) = I(\mathbf{k})$. Consequently, the diffraction has the point group in its symmetry group.

Representations of Space Groups

Euclidean transformations act on positions in space. A quantum mechanical system in such a space has states on which the Euclidean transformations act as linear operators. For example, if the state is given by a wave function $\psi(\mathbf{r})$, the effect of a Euclidean transformation $\{R|\mathbf{t}\}$ gives a new wave function $\psi'(\mathbf{r}) = \psi(R^{-1}(\mathbf{r} - \mathbf{t}))$. This is the action of a linear operator T_g , with $g = \{R|\mathbf{t}\}$. Choosing a basis $\psi(\mathbf{r})$ in the space of states, such a linear operator corresponds to a matrix $D(g)$:

$$T_g \psi_i(\mathbf{r}) = \sum_{j=1}^N D(g)_{ji} \psi_j(\mathbf{r}) \quad [20]$$

(n is the dimension of the state space.) Now the matrices satisfy $D(g_1)D(g_2) = D(g_1g_2)$. This is called a (matrix) representation. If the dimension of the space is n , then the representation is said to be n -dimensional, and the matrices are $n \times n$. These representations are important for characterizing energy levels and other properties. Clearly, the space is mapped onto itself and, therefore, it is invariant under the group of transformations G . If there is no subspace (different from the origin or the whole space) that is invariant, the representation is said to be irreducible. In general, an energy level space carries an irreducible representation of the symmetry group, the dimension of the space is the level degeneracy, and there are orthogonality relations between states from the state space.

This gives a short argument why one should look at the irreducible representations of the space groups. The simplest space group is just a translation group, with three basis translations. Because the order in which translations are applied is not relevant, it is a commutative group, and according to the results of group theory the irreducible representations of commutative groups are one-dimensional, that is the matrices are just numbers. They satisfy $D(\{E|\mathbf{a}\})D(\{E|\mathbf{b}\}) = D(\{E|\mathbf{a}+\mathbf{b}\})$. The solution is $D(\{E|\mathbf{a}\}) = \exp(i\mathbf{k} \cdot \mathbf{a})$ for some vector $\mathbf{k}$. Two vectors $\mathbf{k}$ and $\mathbf{k}'$ give the same representation if $\mathbf{k} - \mathbf{k}'$ belongs to the reciprocal lattice, because then $\mathbf{k} \cdot \mathbf{a} = \mathbf{k}' \cdot \mathbf{a} \pmod{2\pi}$ for all lattice vectors $\mathbf{a}$. Therefore, the irreducible representations are characterized by a vector from the unit cell of the reciprocal lattice. A special choice of this unit cell is the Brillouin zone. It is the unit cell of the reciprocal lattice consisting of all points in reciprocal space which are closer to the origin than to any other point of the reciprocal lattice. Of course, the unit cell of a lattice is not uniquely defined. However, the choice of the Brillouin zone is very convenient when studying electrons or elementary excitations in crystals.

A wave function $\psi(\mathbf{r})$ in a lattice periodic crystal which belongs to an irreducible representation of the lattice subgroup has a special form, the Bloch form, as follows from a group-theoretical argument. Under a translation $\mathbf{a}$, the function transforms to $\psi(\mathbf{r} - \mathbf{a})$ which should be equal to $\exp(i\mathbf{k} \cdot \mathbf{a})\psi(\mathbf{r})$ for some $\mathbf{k}$. Then define $U(\mathbf{r}) = \exp(i\mathbf{k} \cdot \mathbf{r})\psi(\mathbf{r})$. It follows that

$$\begin{aligned} U(\mathbf{r} + \mathbf{a}) &= \exp(i\mathbf{k} \cdot (\mathbf{r} + \mathbf{a}))\psi(\mathbf{r} + \mathbf{a}) \\ &= \exp(i\mathbf{k} \cdot (\mathbf{r} + \mathbf{a}))\exp(-i\mathbf{k} \cdot \mathbf{a})\psi(\mathbf{r}) \\ &= U(\mathbf{r}) \end{aligned}$$

which proves that $\psi(\mathbf{r})$ is the product of a plane wave, $\exp(-i\mathbf{k} \cdot \mathbf{r})$ and a lattice periodic function $U(\mathbf{r})$. This constitutes the well-known Bloch's theorem.

Consider a state space that is invariant under a space group acting on the space by operators T_g for each element g of the space group G . Suppose, furthermore, that the representation is irreducible. The translation subgroup A is a subgroup of G . So, there is a basis formed by functions ψ_i for the space consisting of the eigenvectors of the commuting operators T_a . One has

$$T_a \psi_j = \exp(i\mathbf{k}_j \cdot \mathbf{a})\psi_j \quad [21]$$

A subspace of the space is that belonging to one particular wave vector $\mathbf{k}$. For each state, ψ from this space it holds that $T_a \psi = \exp(i\mathbf{k} \cdot \mathbf{a})\psi$. Applying T_g to any state from this space, ψ transforms to $T_g \psi$. How does this transform under the translations? Applying a translation $\{E|\mathbf{a}\}$ to the transformed vector:

$$\begin{aligned} T_a T_g \psi &= T_g (T_g^{-1} T_a T_g) \psi = T_g T_b \psi \\ &= \exp(-i\mathbf{k} \cdot \mathbf{b}) T_g \psi \end{aligned}$$

Here $\mathbf{b} = R^{-1}\mathbf{a}$ if $g = \{R|\mathbf{t}\}$. The state $T_g \psi$, therefore, acquires a phase factor $\exp(i\mathbf{k} \cdot \mathbf{a})$ and belongs to the subspace of states transforming with a wave vector $R\mathbf{k}$. This means that, if there are states transforming under translations with a wave vector $\mathbf{k}$, then there are, in the irreducible space, states transforming with the wave vector $R\mathbf{k}$ for every point group element. One can write the whole space as a sum of spaces each belonging to a specific $R\mathbf{k}$. One of these spaces is that of states transforming with $\mathbf{k}$.

Now define the subgroup of G consisting of all elements $\{R|\mathbf{t}\}$ for which $R\mathbf{k} = \mathbf{k}$ (modulo the reciprocal lattice because $\mathbf{k}$ and $\mathbf{k} + \mathbf{K}$ give the same representation if $\mathbf{K}$ belongs to the reciprocal lattice). This group is called the group of $\mathbf{k}$: $G_{\mathbf{k}}$. The subspace of states transforming with $\mathbf{k}$ under translations is invariant under the group of $\mathbf{k}$. Then for an element g from the group of $\mathbf{k}$:

$$T_g = \exp(i\mathbf{k} \cdot \mathbf{t}) D_R \quad (g = \{R|\mathbf{t}\})$$

The operators form an irreducible representation of the group of $\mathbf{k}$. For a symmorphic group of $\mathbf{k}$ the elements g can be written as a product $\{E|\mathbf{t}\}\{R|0\}$ of a lattice translation and a point group element. In this case, the operators D_R form an irreducible representation of the point group of the group of $\mathbf{k}$, denoted by $K_{\mathbf{k}}$. These are known, and can be labeled by a label ν . Then a basis of the space of $G_{\mathbf{k}}$ transforms under g as

$$T_g \psi_j = \exp(i\mathbf{k} \cdot \mathbf{t}) D_{hj}(R) \psi_k \quad [22]$$

The basis carries an irreducible representation ν of the point group K (simply take $\mathbf{t}=0$ in the last formula). Here the matrices $D(R)$ are the irreducible representation ν of the point group $K_{\mathbf{k}}$. For nonsymmorphic groups, the procedure is somewhat more complicated, because not only standard representations but projective representations also occur.

Finally, a basis for the full state space can be constructed as follows. The group of $\mathbf{k}$ is a subgroup of the space group G . G can be decomposed according to

$$G = G_{\mathbf{k}} + g_2 G_{\mathbf{k}} + \dots + g_s G_{\mathbf{k}}$$

where the space group elements g_i have homogeneous parts R_i for which $R_i \mathbf{k} = \mathbf{k}_i$. Then the basis is defined as

$$\Psi_{ij} = T_{g_i} \psi_j \quad [23]$$

The dimension of the representation is sd , where s is the number of points $\mathbf{k}_i$, and d the dimension of the point group representation $D(K_{\mathbf{k}})$. The irreducible representation carried by the state space then is characterised by the so-called "star" of $\mathbf{k}$ (all vectors $\mathbf{k}_i$), and an irreducible representation of the point group $K_{\mathbf{k}}$. This means that electronic states and phonons can be characterized by $\mathbf{k}$, ν . Their transformation properties under space group transformations follows from this characterization.

Aperiodic Crystals

Apart from crystals with three-dimensional lattice periodicity, there are materials with a diffraction pattern with sharp Bragg peaks on positions

$$\mathbf{k} = \sum_{i=1}^n h_i \mathbf{a}_i^* \quad (\text{integer } h_i) \quad [24]$$

When $n=3$, the structure is periodic. If $n > 3$, the structure is aperiodic, but it is still considered as crystal, because there is long-range order. Examples are modulated phases and quasicrystals. They may be described as intersections of physical space with a higher-dimensional lattice periodic structure. The symmetry of such structures is a space group in n dimensions, and in this case the theory of space groups in arbitrary dimensions can be used.

Nomenclature

a, b, c	Basis vectors of a lattice
$a, b, c, \alpha, \beta, \gamma$	Lattice parameters
$t; t$	Translation; translation vector
P, A, B, C, I, F, R	Centering types of lattices
$X; \tilde{X}$	Point; transformed point
$x, y, z; \tilde{x}, \tilde{y}, \tilde{z}$	Coordinates of points X and $\tilde{X}$
$r; \tilde{r}$	Location vector; transformed location vector
W	(3×3) matrix, rotation part of a symmetry operation
w	(3×1) column, translation part of a symmetry operation
$W_{ij}; w_k$	Elements of W and w
$\mathbb{W}, \mathbb{T}, \mathbb{P}$	(4×4) augmented matrix; (4×4) augmented matrix of pure translation; (4×1) augmented vector
(hkl)	Miller indices of a crystal face (lattice plane)
$[uvw]$	Direction indices of a crystal edge (lattice direction)

Schoenflies Symbols

$C_n = C_1, C_2, C_3, C_4, C_6$	Cyclic group of order $n = 1, 2, 3, 4, 6$
$C_s; C_i$	Reflection group; inversion group (order 2)
S_4	Rotoinversion (rotoreflexion) group of order 4
$D_n = D_2, D_3, D_4, D_6$	Dihedral group of order $m = 2n = 4, 6, 8, 12$
T	Tetrahedral group (order 12)
O	Octahedral group (order 24)

Hermann–Mauguin (International) Symbols

$n=1, 2, 3, 4, 6$	n -fold rotation axes (order n)
$\bar{n}, \bar{1}, \bar{2} \equiv m,$	n -fold rotoinversion axes
$\bar{4}, \bar{3}, \bar{6} \equiv 3/m$	(orders 2, 2, 4, 6, 6, resp.)
$n_p=2_1, 3_1, 3_2, 4_1, 4_2, 4_3, 6_1, 6_2, 6_3, 6_4, 6_5$	n -fold screw axes (order ∞)
$m(\equiv 2)$	reflection (mirror) plane (order 2)
a, b, c, n, d	glide reflection planes (order ∞)
g	glide line (two dimensions, order ∞)

Introduction

Among the various states of condensed matter, the crystalline state is governed by symmetry more than any other state (e.g., liquids, glasses). This is because all atoms of one type in a solid compound display the same structural behavior and adopt, as far as possible, the same atomic environment around them. This applies to all kinds of atoms in the compound and results from the tendency of any system to minimize its free energy. As a first consequence, this leads to three-dimensional periodicity (translational symmetry) of the atoms (ions, molecules) in a crystal structure. As a second consequence, further symmetries, such as rotations, reflections, and inversions (through a point), may occur.

As a rule, symmetry in science is described mathematically in terms of the “group theory.” For crystals, the main symmetry groups are point groups, translation groups, and space groups (these are discussed elsewhere in this encyclopedia). Group elements are the symmetry operations discussed in the section “Crystallographic symmetry operations and symmetry elements.” Fundamentals of crystallography and of crystallographic symmetry groups can be found in text books of crystallography and in *ITA* (2002) (cf. section “Further reading”).

Two levels of crystalline symmetry must be distinguished:

1. “Microscopic” symmetry of the crystal structure: this implies a three-dimensional periodicity which is described by translation groups and their lattices. Furthermore, all permissible combinations of translations with reflections, rotations and inversions, including screw rotations and glide reflections, can occur as elements of space groups.
2. “Macroscopic” symmetry of the single (bulk) crystal: it is derived from the microscopic symmetry (space group) of the crystal structure by the suppression of all translations, both lattice translations and translation components of screw rotations and glide reflections. This leads to the point group of the crystal, which represents its morphological symmetry as manifested by the general face form, which may develop under ideal conditions during crystal growth. Furthermore, the symmetry of physical properties of crystals, in particular of tensor properties, is also described by point groups. Note that in this description, the macroscopic crystal is considered as an anisotropic homogeneous continuum.

Lattices and Their Symmetries

The symmetry operations of a crystal are “isometries” or “rigid motions”, that is, mappings which preserve distances and, hence, angles and volumes also. The simplest motion is a translation which is a parallel displacement of an object by a translation vector t . The three-dimensional periodicity (translation symmetry) of the (infinitely extended) crystal structure is described by the infinite set $\{t\}$ of all translation vectors t mapping the structure onto itself, that is, by the lattice. It is represented by the equation

$$\{t\} = \{m \cdot a + n \cdot b + p \cdot c\} (-\infty < m, n, p < +\infty) \quad [1]$$

with a, b, c three linearly independent basis vectors spanning a three-dimensional parallelepiped called unit cell. Each translation t maps the crystal structure onto itself and is, hence, a symmetry operation of the crystal.

Equation [1] implies that for a given basis vector set a, b, c , one unique lattice $\{t\}$ is defined. On the other hand, one and the same lattice can be generated by infinitely many different triplets a', b', c' of linearly independent lattice vectors, each triplet spanning a “primitive” (smallest) unit cell (this triplet is called “primitive basis” here). All these triplets are equally correct lattice bases. As will be shown below, one (or at most two) particularly symmetry-adapted basis vector sets are conventionally accepted by all scientists.

There exist four different types of lattice symmetries in two dimensions and seven in three dimensions. These so-called “lattice point symmetries” are defined as the symmetries of the infinite surrounding of each lattice point by the other lattice points. These lattice symmetries are also called “holohedries” (holohedral point groups), a term which stems from the old morphological classification, meaning “full face form.” These holohedries determine the seven three-dimensional crystal systems and crystallographic coordinate systems: triclinic (anorthic), monoclinic, orthorhombic, tetragonal, trigonal/rhombohedral, hexagonal, cubic (see Table 1, see footnote there about trigonal/rhombohedral). Geometrically, these holohedral lattice symmetries are brought out directly in the so-called “Wigner–Seitz cells” or “Dirichlet domains” (see *ITA* (2002)).

Table 1 Crystal systems, lattice point symmetries, conventional crystallographic coordinate systems and Bravais lattice types in two and three dimensions. The lattice point symmetries (column 2) are given in Hermann–Mauguin (left) and in Schoenflies symbols (right); see Section “Symbols for point groups and space groups”

^aBravais lattices (column 4): The lower-case first letter of the symbol identifies the crystal system. Note that the trigonal and the hexagonal system both receive the letter *h*. Second letter of the symbol: *p, c* in two dimensions: primitive and centered cell. Three dimensions: *P* = primitive cell; *A, B, C* = one-face centered cell on (*b, c*), (*a, c*) or (*a, b*) face; *I* = body centered cell; *F* = all-face centered cell; *R* = rhombohedral centering of the hexagonal cell.

^bIn the trigonal crystal system two Bravais lattices, *hR* and *hP*, with different holohedries, $\bar{3}2/m$ and $6/m2/m2/m$, occur. Both are normally described by “hexagonal axes.”

Crystallographic Coordinate Systems

“Primitive” Crystallographic Coordinate Systems

Whereas in physics and chemistry normally Cartesian coordinate systems are used, in crystallography quite different systems are applied. Here it is customary that every crystal receives its own specific crystallographic coordinate system, based on the symmetry of the crystal and characterized as follows:

1. Basis vectors are three linearly independent, shortest (“primitive”) translation vectors of the crystal lattice (see eqn [1]). This implies six lattice parameters: three axial lengths a, b, c , and three interaxial angles α, β, γ . (“Primitive” means that the unit cell spanned by the three basis vectors contains only one lattice point, in contrast to “centered cells,” see the next section.)
2. The origin of the coordinate system is free in principle, but for convenience in computation, it is usually chosen in a center of symmetry (inversion center), if present, otherwise in a point of high site symmetry of the space group (e.g., in an intersection of two or more symmetry axes).

The advantage of such a crystal-specific coordinate system is that all lattice points receive integer coordinates, and this applies to all choices of a primitive coordinate system for a given crystal. Note that the lattice parameters of a crystal vary with temperature and pressure.

Conventional Crystallographic Coordinate Systems

In order to define a unique crystallographic coordinate system for each crystal, special conventions have to be devised. It turns out, however, that the use of a special primitive coordinate system, as described in the preceding section, would indeed always characterize the crystal lattice uniquely, but in many cases would not bring out the symmetry of the crystal. This, however, is a universally accepted objective for the definition of the conventional crystallographic coordinate system in the form of a symmetrical parallelepiped as unit cell.

For this reason, the 14 Bravais types of lattices are considered, with the provision that all Bravais lattices with the same holohedry should have the same conventional coordinate system. A consequence of this procedure is that only for primitive Bravais lattices, all lattice points receive integer coordinates, whereas for centered lattices of the same lattice, symmetry points with fractional coordinates $1/2$, $1/3$, and $2/3$ (and no others) appear. In this way, seven conventional coordinate systems result, which apply to the crystals of all 14 Bravais lattice types. As a typical example, the cubic crystal system is considered: for the primitive cubic lattice cP , the conventional coordinate system employs the three shortest lattice vectors with right interaxial angles $\alpha = \beta = \gamma = 90^\circ$. In this case, the conventional coordinate system is at the same time a primitive crystallographic basis. For the body-centered and all-face-centered cubic Bravais lattices cI and cF , however, only a fraction of the lattice points ($1/2$ for cI and $1/4$ for cF) have integer coordinates represented by 0,0,0, whereas the remaining centering lattice points have fractional coordinates: $1/2$, $1/2$, $1/2$ for cI , and $1/2$, $1/2$, 0 & 0, $1/2$, $1/2$ & $1/2$, 0, $1/2$ for cF . If only primitive cells were used, the coordinate system for cP would remain the same (cube = 90° rhombohedron), whereas for cI and cF rhombohedral cells with $\alpha = 109.47^\circ$ and $\alpha = 60^\circ$, respectively would result which would not display the cubic symmetry.

The conventional crystallographic coordinate systems are collected in Table 1, which lists the four plane and the seven spatial lattice symmetries with their point-group symbols and the restrictions on the general lattice parameters $a, b, c, \alpha, \beta, \gamma$ imposed by the lattice symmetry. The symbols of the Bravais lattices which belong to a given coordinate system are listed too. These symmetry criteria uniquely determine five of the seven three-dimensional coordinate systems because these five exhibit three or more symmetry directions ("blickrichtungen"): orthorhombic, tetragonal, rhombohedral, hexagonal, cubic. For the two exceptions, triclinic and monoclinic, no or only one symmetry direction exists. In these cases, metrical criteria, such as reduced bases (i.e., choice of the three (triclinic) or two (monoclinic) shortest lattice translations as basis vectors), have to be applied. It should be noted that for historical reasons, in the monoclinic system two different "settings" are in use, which are distinguished by the labeling of the unique symmetry axis: "unique axis b " and "unique axis c " settings. The b -axis setting is the more frequently used one (see Part 2 of ITA (2002)).

There is one case in which not one but two different conventional coordinate systems are in use, for trigonal crystals with a rhombohedral hR lattice. These crystals are alternatively described by "rhombohedral axes" or, more frequently, by "hexagonal axes," whereby the first case corresponds to a primitive rhombohedral unit cell, the second to the triple R-centered hexagonal unit cell. In contrast, crystals with a hexagonal hP lattice are always described by "hexagonal axes."

Detailed descriptions of the conventional crystallographic coordinate systems and reduced bases can be found in sections 1.2, 2.1, 8.3.1, 9.1 and 9.2 of ITA (2002).

Crystallographic Symmetry Operations and Symmetry Elements

Symmetry Operations

The following types of symmetry operations exist in crystals and are elements of crystallographic symmetry groups:

1. Translations (already treated in the section "Lattices and their symmetries").
2. Rotations around an axis, reflections across a plane and inversions in a point, as well as their combinations, that is, rotoinversions and roto reflections. These operations constitute the so-called point-group operations, which leave at least one point of space invariant.
3. Combinations between point-group operations and translations, leading to screw rotations and glide reflections. Both types occur only in space groups, not in point groups. Screw rotations are rotations by an angle $\varphi = 360^\circ/n$, followed by a translation (screw component) parallel to the rotation axis. Glide reflections are reflections across a plane, followed by a translation (glide component) parallel to the plane. The screw and glide components are rational fractions of a lattice translation.

An important fact of crystallographic symmetry is the restriction of the rotation angles φ by the translation lattice to $\varphi = 180^\circ, 120^\circ, 90^\circ, 60^\circ$, defining twofold, threefold, fourfold, and sixfold rotations and screw rotations. This is the consequence of the three-dimensional periodicity of crystals. Apart from a simple mathematical proof (see section "Matrix representation of symmetry operations"), this result is immediately obvious from the fact that a plane can be covered without gaps and overlaps only by parallelograms and their special forms (rectangles, rhombuses, squares), and by triangles and hexagons, but not by pentagons (corresponding to a rotation angle of 72°), heptagons, octagons, etc. Hence, rotation axes other than two-, three-, four-, and sixfold axes are not possible in crystals.

Symmetry Elements

In addition to symmetry operations (which represent "action" on an object), symmetry can also be described in (static) geometrical terms, known as symmetry elements. They form the geometric locus (geometric element), oriented in space, at which a symmetry operation or a cyclic group of operations is performed (plane for a reflection, line for a rotation, point for an inversion), together with a description of these operations. In other words, the symmetry element is the "invariant subspace" of a given operation, that is, the set of fixed points which are invariant under the operation.

Symmetry elements are reflection (mirror) planes, glide planes, rotation axes, screw axes and centers of symmetry. For rotoinversions and roto reflections, the symmetry element consists of two items: axis and inversion point on the axis, or axis and

mirror plane normal to the axis. For screw rotations and glide reflections, the screw and glide components have to be removed first in order to obtain the “fixed points” for screw axes and glide reflections.

Note that the group elements of a symmetry group are the symmetry operations, not the symmetry elements. This discrepancy of nomenclature has historical reasons and is the source of frequent misunderstandings.

The crystallographic symmetry elements (reflection and glide plane, rotation and screw axes, and rotoinversion axes) are illustrated in Figures 1–3. Printed and graphical symbols of all symmetry elements are collected in Table 2. Further details are given in Parts 1 and 8.1 of *ITA* (2002) and the references quoted therein. Complete “frameworks of symmetry elements” for the 17 plane groups, the 230 space groups, and the 32 crystallographic point groups are presented in Parts 6, 7 and 10.1 (and explained in section 2.2.6) of *ITA* (2002).

Figure 1 Symmetry elements in crystals: twofold rotation and screw axes 2 and 2_1 (left pair), and reflection and glide planes m and c (right pair). The “objects” are polar two-atomic molecules, in order to bring out the orientational differences between rotations and reflections. Note that each diagram extends over two translation periods along c . The graphical symbols underneath the diagrams are explained in Table 2.

Figure 2 Symmetry elements in crystals: threefold rotation and screw axes (top row), fourfold rotation and screw axes (top row), and sixfold rotation and screw axes (bottom row). Each diagram extends over two translation periods along c . For the screw axes 3_1 and 3_2 , the course of the screws (helices) is indicated in order to show the enantiomorphism (mirror images) of the two screw axes. The subelements (subgroups) of each symmetry element (cyclic group) are given in parentheses. The graphical symbols are explained in Table 2.

Figure 3 Symmetry elements in crystals: the five crystallographic rotoinversion axes $\bar{1}\bar{2}\bar{4}\bar{3}\bar{6}$ (orders 2, 2, 4, 6, 6, resp.), and their action on a spherical object. Starting from object 1, objects 2, 3, ... are successively generated. The intermediate positions of the object (between the rotation and the inversion part of the operation) are labeled by numbers in parentheses. For all groups the first operation $1 \rightarrow (2') \rightarrow 2$ is indicated by dashed arrows. The labels R and L denote the handedness (right or left), if the object is chiral (starting object 1: R). All odd powers of rotoinversions are hand-changing ($R \rightarrow L$), even powers hand-preserving ($R \rightarrow R$, $L \rightarrow L$). Note that for axes $\bar{n}$ with n odd (i.e., for $\bar{1}$ and $\bar{3}$), the inversion point is a center of symmetry $\bar{1}$ (i.e., a subelement). For axes $\bar{n}$ with $n = 4k + 2$ (i.e., $\bar{2}$ and $\bar{6}$), a mirror plane m normal to the axis and intersecting the inversion point is a subelement, whereas for $n = 4k$ (i.e., $\bar{4}$) neither $\bar{1}$ nor m occur as subelements. The subelements of the rotoinversion axes are noted in parentheses.

Matrix Representation of Symmetry Operations

General Relations

In the mathematical treatment of symmetry operations, normally the coordinate system, that is, the set of basis vectors a, b, c and the origin, is considered to be at rest, whereas the object is mapped onto itself (special affine mapping). (Equivalently, it is equally correct to transform the coordinate system, whereby the object is considered to be at rest.) A general symmetry operation transforms a point X with coordinates x, y, z into a symmetrically equivalent point X' , with coordinates x', y', z' according to

$$\begin{aligned}\tilde{x} &= W_{11}x + W_{12}y + W_{13}z + w_1 \\ \tilde{y} &= W_{21}x + W_{22}y + W_{23}z + w_2 \\ \tilde{z} &= W_{31}x + W_{32}y + W_{33}z + w_3\end{aligned}\quad [2]$$

or, in matrix notation:

$$\begin{pmatrix} \tilde{x} \\ \tilde{y} \\ \tilde{z} \end{pmatrix} = \begin{pmatrix} W_{11} & W_{12} & W_{13} \\ W_{21} & W_{22} & W_{23} \\ W_{31} & W_{32} & W_{33} \end{pmatrix} \cdot \begin{pmatrix} x \\ y \\ z \end{pmatrix} + \begin{pmatrix} w_1 \\ w_2 \\ w_3 \end{pmatrix}\quad [3]$$

$$\tilde{r} = W \cdot r + w = (W, w) \cdot r$$

The (3×3) matrix W is the rotation part, and the (3×1) column matrix w , the translation part of the symmetry operation. The matrices W represent all point-group operations, rotations, reflections, inversions, and rotoinversions. The two parts W and w can be assembled into an (augmented) (4×4) matrix $\mathbb{W}$ according to

Table 2 Printed and graphical symbols for symmetry elements in two and three dimensions. For glide planes only a few selected examples are given

Printed symbol	Symmetry element and its orientation, glide and screw vectors $\mathbf{t}$	Graphical symbol normal to plane of projection
m	Reflection (mirror) plane (three dimensions) Reflection (mirror) line (two-dimensions)	
$a, b, \text{ or } c$	“Axial” glide plane	
a	$\perp [0\ 1\ 0]$ or $\perp [0\ 0\ 1]$ $\mathbf{t} = 1/2\mathbf{a}$ }	
b	$\perp [1\ 0\ 0]$ or $\perp [0\ 0\ 1]$ $\mathbf{t} = 1/2\mathbf{b}$ }	
c	$\perp [1\ 0\ 0]$ or $\perp [0\ 1\ 0]$ $\mathbf{t} = 1/2\mathbf{c}$	
g	Glide line (two dimensions) $\perp [0\ 1]$; $\perp [1\ 0]$; $\mathbf{t} = 1/2\mathbf{a}$; $1/2\mathbf{b}$ (resp.)	
n	“Diagonal” glide plane $\perp [0\ 0\ 1]$; $\perp [1\ 0\ 0]$; $\perp [0\ 1\ 0]$; $\mathbf{t} = 1/2(\mathbf{a} + \mathbf{b})$; $1/2(\mathbf{b} + \mathbf{c})$; $1/2(\mathbf{a} + \mathbf{c})$ (resp.)	
d	“Diamond” glide plane (pair of planes) Orthorhombic: $\perp [0\ 0\ 1]$; $\perp [1\ 0\ 0]$; $\perp [0\ 1\ 0]$; $\mathbf{t} = 1/4(\mathbf{a} \pm \mathbf{b})$; $1/4(\mathbf{b} \pm \mathbf{c})$; $1/4(\mathbf{c} \pm \mathbf{a})$ (resp.) Cubic (examples): $\perp [1\ 1\ 0]$; $\perp [0\ 1\ 1]$; $\perp [1\ 0\ 1]$; $\mathbf{t} = 1/4(-\mathbf{a} + \mathbf{b} \pm \mathbf{c})$; $1/4(\pm \mathbf{a} - \mathbf{b} + \mathbf{c})$; $1/4(\mathbf{a} \pm \mathbf{b} - \mathbf{c})$ (resp.)	
1	None (identity)	
$2, 3, 4, 6$	n -fold rotation axis, n (three dimensions) n -fold rotation point, n (two dimensions)	
$\bar{1}$	Center of symmetry, inversion center	
$\bar{2} = m, \bar{3}, \bar{4}, \bar{6}$	Rotoinversion axis, $\bar{n}$, with inversion point on the axis ^a	
2_1	n -fold screw axis, n_p The screw component is the fraction p/n $\mathbf{t}$ of the shortest lattice translation $\mathbf{t}$ parallel to the axis	
$3_1, 3_2$		
$4_1, 4_2, 4_3$		
$6_1, 6_2, 6_3, 6_4, 6_5$		

^aThe inversion point is a center of symmetry (inversion center) if n is odd.

Notes: 1. The graphical symbols (column 3) refer to planes and axes oriented normal to the plane of projection.

2. Diamond glide planes d occur only in orthorhombic F space groups, in tetragonal I space groups, and in cubic I and F space groups. They always occur in pairs with alternating vectors, for instance, $1/4(\mathbf{a} + \mathbf{b})$ and $1/4(\mathbf{a} - \mathbf{b})$. The second power of a glide reflection d (i.e., the result of two successive applications) is a lattice centering vector. The name “diamond glide” is due to its pronounced occurrence in the diamond structure.

3. Rotoreflections are not listed here, because they correspond to rotoinversions according to the following scheme: two-, three-, four-, and sixfold roto reflections are identical with the rotoinversions $\bar{1}$ (inversion), $\bar{6}$, $\bar{4}$ and $\bar{3}$, respectively. Note that the even two- and sixfold roto reflections (corresponding to the odd rotoinversions $\bar{1}$ and $\bar{3}$) contain a symmetry (inversion) center.

4. The following pairs of screw axes are “enantiomorphic,” i.e. each pair consists of a right- and a left-handed screw axis: $(3_1, 3_2)$, $(4_1, 4_3)$, $(6_1, 6_5)$ and $(6_2, 6_4)$. The screw axes 2_1 , 4_2 , 6_3 are “neutral.” Note that all rotation and screw axes may accommodate enantiomorphic structures, whenever the building units (atomic groups, molecules) of the structure are “chiral,” i.e., either all right- or all left-handed.

5. A right-handed screw rotation is customarily defined as a counter-clockwise rotation with the screw vector pointing toward the observer.

$$\begin{aligned}
 \begin{pmatrix} \tilde{x} \\ \tilde{y} \\ \tilde{z} \\ 1 \end{pmatrix} &= \begin{pmatrix} W_{11} & W_{12} & W_{13} & w_1 \\ W_{21} & W_{22} & W_{23} & w_2 \\ W_{31} & W_{32} & W_{33} & w_3 \\ 0 & 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \\
 &= \begin{pmatrix} W & w \\ 0 & 0 & 0 & 1 \end{pmatrix} \cdot \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} = \mathbb{W} \cdot r
 \end{aligned}$$

[4]

Since every symmetry transformation is a “rigid-body motion,” the determinant of the matrices W and $\mathbb{W}$ is

$$\det W = \det \mathbb{W} = 1 \quad [5]$$

The sequence of two symmetry operations (successive application) is given by the product of their (4×4) matrices $\mathbb{W}_1$ and $\mathbb{W}_2$:

$$\mathbb{W}_3 = \mathbb{W}_2 \cdot \mathbb{W}_1 \quad [6]$$

whereby, $\mathbb{W}_3$ is again a symmetry operation.

The inverse operation $\mathbb{W}^{-1}$ is defined by $\mathbb{W} \cdot \mathbb{W}^{-1} = \mathbb{I}$, whereby $\mathbb{W}$ is the (4×4) unit matrix representing the identity operation:

$$\mathbb{W}^{-1} = \begin{pmatrix} W^{-1} & -W^{-1} \cdot w \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

[7]

Finally, the augmented matrix for a translation t is

$$\begin{aligned}
 \mathbb{T} &= \begin{pmatrix} I & t \\ 0 & 0 & 0 & 1 \end{pmatrix}, \\
 t &= \begin{pmatrix} t_1 \\ t_2 \\ t_3 \end{pmatrix}
 \end{aligned}$$

[8]

and I the (3×3) unit matrix.

Note on the matrices W and $\mathbb{W}$ of eqns [3] and [4]: The rotation parts W of these matrices leave an atom located in the origin of the coordinate system invariant, that is, the symmetry element of W intersects the origin. The translation parts w consist of two components, first the (intrinsic) “screw or glide component” of a screw rotation or glide reflection (if present), second the “location parameter,” which depends on the location of the symmetry element with respect to the origin. Thus, for a pure rotation or reflection through the origin, $w = w_1, w_2, w_3 = (0, 0, 0)$.

Geometric Interpretation of (Crystallographic) Symmetry Matrices

A (3×3) matrix W of a rigid motion has two essential invariants, that is, two quantities which do not change under a transformation of the coordinate system and, hence, can serve to identify the “nature” of the motion. These quantities are the determinant, $\det W$, and the trace, $\text{tr} W W_{11} + W_{22} + W_{33}$. Their properties are as follows:

1. A rotation by an angle φ and its representation in a Cartesian coordinate system x_1, x_2, x_3 are assumed, whereby the rotation axis intersects the origin and is parallel to x_3 . The rotation matrix is

$$W = \begin{pmatrix} \cos \phi & \sin \phi & 0 \\ -\sin \phi & \cos \phi & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

The trace is $\text{tr } W = 1 + 2 \cos \varphi$, valid for any coordinate system. Since this rotation maps a lattice point with integer coordinates onto another lattice point, all elements of the matrix, if referred to a crystallographic coordinate system, must be integers, hence $\text{tr } W = 1 + 2 \cos \varphi = m$, and $\cos \varphi = 1/2(m - 1) = 1/2p$ (m, p integers). Since $\cos \varphi$ is restricted to the range -1 to $+1$, only the following values of $\cos \varphi$ are compatible with lattice symmetry: $\cos \varphi = +1, +1/2, 0, -1/2, -1$, corresponding to rotation angles of $0^\circ \equiv 360^\circ, 60^\circ, 90^\circ, 120^\circ$, and 180° . This is the famous “crystallographic restriction,” which filters out the five permissible φ -angles (and their multiples) from the infinity of “ n -fold rotations” with $\varphi = 360^\circ/n$.

- Since symmetry operations are rigid motions which preserve distances, angles, and volumes, the determinant of their matrices must be $+1$ or -1 :

$\det W = +1$: rotation; handedness (left or right) of object retained;

$\det W = -1$: reflection, inversion, rotoinversion : handedness of object reversed;

- By combining the possible values of $\det W$ and $\text{tr } W$, the “nature” of a symmetry operation by means of its (3×3) symmetry matrix W is identified, as shown in Table 3.
- By more detailed analysis of the (3×3) “point-group” matrices W and the augmented (4×4) “space-group” matrices $\mathbb{W}$, further characteristics of symmetry operations can be derived, that is, the orientation of the axis or of the plane in the given coordinate system, as well as the location of the symmetry element (plane, axis, point) in the unit cell relative to the chosen origin (see *ITA* (2002), Part 11).
- In order to illustrate the previous somewhat abstract considerations, some examples of (4×4) matrices for (glide) reflections and (screw) rotations, together with their geometric elements, are given in Table 4. A list of all (3×3) matrices occurring in crystallographic point and space groups is available in Part 11 of *ITA* (2002).

Table 3 Crystallographic symmetry operations as derived from their traces $\text{tr } W$ and determinants $\det W = +1$ and -1

	$\det W = +1$					$\det W = -1$				
$\text{tr } W$	+1	+1/2	0	-1/2	-1	+1	+1/2	0	-1/2	-1
<i>H.-Mauguin</i> symbol of operation	1	6	4	3	2	$\bar{1}$	$6 \equiv 3/m$	4	$\bar{3}$	$2 \equiv m$
<i>Schoenflies</i> symbol of operation	C_1	C_6	C_4	C_3	C_2	C_i	C_{3h}	S_4	C_{3i}	C_s
Order n of operation ^a	1	6	4	3	2	2	6	4	6	2

^aThe “order” n of the operation W is the order of the cyclic group generated by W , i.e., the power n of W for which the identity 1 is reached: $W^n = 1$.

Table 4 Examples of augmented (4×4) matrices of symmetry operations (referred to the appropriate conventional coordinate system)^a

Inversion with center in x_0, y_0, z_0 $\begin{pmatrix} -1 & 0 & 0 & 2x_0 \\ 0 & -1 & 0 & 2y_0 \\ 0 & 0 & -1 & 2z_0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$	Twofold rotation along z in x_0, y_0, z $\begin{pmatrix} -1 & 0 & 0 & 2x_0 \\ 0 & -1 & 0 & 2y_0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$	Twofold screw rotation along z in x_0, y_0, z $\begin{pmatrix} -1 & 0 & 0 & 2x_0 \\ 0 & -1 & 0 & 2y_0 \\ 0 & 0 & 1 & 1/2 \\ 0 & 0 & 0 & 1 \end{pmatrix}$
Glide reflection n with plane $\perp x$ in x_0, y, z $\begin{pmatrix} -1 & 0 & 0 & 2x_0 \\ 0 & 1 & 0 & 1/2 \\ 0 & 0 & 1 & 1/2 \\ 0 & 0 & 0 & 1 \end{pmatrix}$	Fourfold (screw) rotation 4_p with $p=0, 1, 2, 3$ along z in $0, 0, z$ (§) $\begin{pmatrix} 0 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & p/4 \\ 0 & 0 & 0 & 1 \end{pmatrix}$	Fourfold rotoinversion $\bar{4}$ along z in $0, 0, z$ $\begin{pmatrix} 0 & 1 & 0 & 0 \\ -1 & 0 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$
Threefold (screw) rotation 3_p with $p=0, 1, 2$ along z in $0, 0, z$ (§) $\begin{pmatrix} 0 & -1 & 0 & 0 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & 1 & p/3 \\ 0 & 0 & 0 & 1 \end{pmatrix}$	Sixfold (screw) rotation 6_p with $p=0, 1, 2, 3, 4, 5$ along z in $0, 0, z$ (§) $\begin{pmatrix} 1 & -1 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & p/6 \\ 0 & 0 & 0 & 1 \end{pmatrix}$	Threefold rotation 3 around body diagonal x, x, x (cubic system) (#) $\begin{pmatrix} 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$

(§) Note that $p=0$ stands for a normal (nonscrew) rotation.

(#) Cyclic permutation of the coordinates. This matrix also represents the one threefold rotation around x, x, x in the rhombohedral coordinate system. There are four equivalent cubic body diagonals x, x, x ; $-x, x, x$; $x, -x, x$ and $x, x, -x$ with different cyclic permutations of $+1$ and -1 .

^aThe matrices in this table represent the “first powers” of the operations. Higher powers are obtained by repeated multiplication of the matrix. For point-group operations of order 2 (“binary” operations: inversions, twofold rotations, reflections), the second power is the identity, i.e., binary operations are their own inverses.

6. It should be noted that in quasicrystals (i.e., forms of solid matter not based on exact three-dimensional periodicity but rather on “quasiperiodicity”), symmetries may occur which go beyond the “crystallographic restriction” discussed above under point 1. For instance, quasicrystals with icosahedral symmetry (containing fivefold rotations), as well as with tenfold and twelvefold rotations have been found.

Symbols for Point Groups and Space Groups

So far, “individual” symmetry operations and symmetry elements have been treated with their printed and graphical symbols, see Table 2. In order to combine these into symbols for crystallographic point and space groups, rules for the combination have to be specified. There are two types of group symbols in use: the oldest are the Schoenflies symbols contained in Schoenflies’ classic work of 1891. The second are the Hermann-Mauguin symbols, derived around 1928 in several papers by Hermann and Mauguin. The latter are now predominantly used in crystallography and crystal-structure analysis, and are customarily called “international symbols.” Schoenflies symbols are often preferred in spectroscopy and in studies of molecules.

Schoenflies Symbols

These symbols are based on group theory and use capital letters to indicate the major types of symmetry groups.

C: Cyclic groups C_1, C_2, C_3, C_4, C_6 of order $C_1 = 1, 2, 3, 4$ and 6;

C_s =reflection group (s =*Spiegelsymmetry*) of order 2;

C_i = inversion group of order 2;

D: Dihedral groups D_2, D_3, D_4, D_6 , that is, a cyclic group C with additional twofold rotation axes normal to the main symmetry axis. The order m of these groups is twice that of the corresponding C_n group: $m = 2n$.

T: Tetrahedral group (order $n = 12$);

O: Octahedral group (order $n = 24$).

Subscripts h, v , and d indicate the presence of mirror planes perpendicular h = horizontal and parallel (v = vertical, d = diagonal) to the main symmetry axis, which is considered to be vertical, for example, $C_{2h}, D_{4h}, T_h, O_{2v}, C_{6v}, D_{3d}$. The Schoenflies symbols are independent of any coordinate system.

These symbols apply to three-dimensional crystallographic point groups. Space groups are indicated by superscripts added to the corresponding point-group symbols, for example, $C_{2h}^5, D_2^4, D_{2h}^{16}, T_h^7, O_h^9$. This implies that the Schoenflies symbols carry no information about the nature of the space group. No Schoenflies symbols exist for two-dimensional groups.

Hermann–Mauguin (International) Symbols

These symbols have, as their basis, the seven different point symmetries of the Bravais lattices. Every lattice, if viewed along a general direction, exhibits only inversion symmetry $\bar{1}$. There are, however, between zero (tridinic) and 13 (cubic) specific directions, along which symmetries above $\bar{1}$ are seen. These so-called “lattice symmetry directions” (blickrichtungen) and the symmetries seen along them are characteristic for the seven types of lattice symmetries (holohedries), see Table 1. They can be grouped into none (tridinic), one (monoclinic), two (rhombohedral), and three (all other lattices) classes of equivalent symmetry directions (e.g., the fourfold cubic rotation axes $[1\ 0\ 0], [0\ 1\ 0], [0\ 0\ 1]$ form one class). These classes are arranged in a well-defined sequence (called “positions”), which is again characteristic for each crystal system. They form, thus, the basis of the Hermann–Mauguin (international) point-group and space-group symbols.

The representative lattice symmetry directions for these classes are presented in Table 5, both for two- and three-dimensional lattices. The three columns define the “position” of an entry in a Hermann–Mauguin group symbol (primary, secondary, and tertiary position). The entries in an actual symbol are those symmetry axes and symmetry planes, which are “observed” for the corresponding blickrichtung. A slash indicates the occurrence of a mirror (glide) plane perpendicular to an axis (e.g., $4/m, 2_1/c$). In this way, the international point-group symbols are obtained. This process is illustrated, first for “point groups,” by the following examples:

1, $\bar{1}$	triclinic; no symmetry direction, since $\{\bar{1}\}$ is a point (Schoenflies symbols C_1, C_i);
2, $m, 2/m$	monoclinic; only one symmetry direction along which is “seen” a twofold axis, the normal to a mirror plane or the combination of both (Schoenflies symbols C_2, C_s, C_{2h});
$mm2$	orthorhombic; three perpendicular symmetry directions, two of which carry normals to mirror planes, the third a twofold axis (Schoenflies symbol C_{2v});
$4/m$	tetragonal, short for $4/m\bar{1}1$, since only the primary blickrichtung carries symmetry (Schoenflies symbol C_{4h});
$6/m2/m2/m$ (short: $6/mmm$)	hexagonal holohedry; three classes of symmetry directions, the primary single direction is populated by a sixfold rotation axis and a perpendicular mirror plane: $6/m$. The three equivalent secondary and three equivalent tertiary directions are populated by twofold axes with perpendicular mirror planes, leading to a total of seven “occupied” blickrichtungen (Schoenflies symbol D_{6h});
$4/m\bar{3}2/m$ (short: $m\bar{3}m$)	cubic holohedry; point group of highest crystallographic symmetry; along the three cube edges of the cubic unit cell, symmetry axes/planes $4/m$ occur, the four body-diagonal directions of the cube are populated by $\{\bar{1}\}$ inversion axes, and the six face diagonals carry $2/m$ symmetries. In total, there are 13 symmetry directions with 48 symmetry operations (=group order) (Schoenflies symbol O_h).

Table 5 Representative lattice symmetry directions for two and three dimensions. The number in parentheses refers to the number of equivalent symmetry directions of the given set, e.g., cubic [1 0 0] (3) refers to the three equivalent directions [1 0 0], [0 1 0], [0 0 1]

Lattice	Symmetry direction (position in Hermann–Mauguin symbol)		
	Primary	Secondary	Tertiary
<i>Two dimensions</i>			
Oblique (monoclinic)	Rotation	-----	-----
Rectangular (orthorhombic)	point	[1 0] (1)	[0 1] (1)
Square (tetragonal)	ln	[1 0] (2)	[1 $\bar{1}$] (2)
Hexagonal	plane (1)	[1 0] (3)	[1 $\bar{1}$] (3)
<i>Three dimensions</i>			
Triclinic (anorthic)	None		
Monoclinic	[0 1 0] (1) (unique axis <i>b</i>) [0 0 1] (1) (unique axis <i>c</i>)	-----	-----
Orthorhombic	[1 0 0] (1)	[0 1 0] (1)	[0 0 1] (1)
Tetragonal	[0 0 1] (1)	[1 0 0] (2)	[1 $\bar{1}$ 0] (2)
Hexagonal	[0 0 1] (1)	[1 0 0] (3)	[1 $\bar{1}$ 0] (3)
Rhombohedral (hexagonal axes)	[0 0 1] (1)	[1 0 0] (3)	-----
Rhombohedral (rhombohedral axes)	[1 1 1] (1)	[1 $\bar{1}$ 0] (3)	-----
Cubic	[1 0 0] (3)	[1 1 1] (4)	[1 $\bar{1}$ 0] (6)

The space-group symbols are modifications of the point-group symbols in two ways: first, the letter with the centering type of the appropriate Bravais lattice, *P*, *A*, *B*, *C*, *I*, *F*, *R* is added in front of the symbol. Second, as appropriate, the symbols for rotation axes are substituted by those of screw axes, and the symbols of reflection planes by those of glide planes. Lattice symmetry directions, which do not carry any symmetry, are represented by the symbol “1”, as in *P31m* and *P3m1*, or are left empty as in *P6₃/m*, short for *P6₃/m11*.

This procedure leads to the following full (and short) symbols, given as examples:

Monoclinic: *P2₁/c*, *C2/c* (two of the frequently encountered space groups);

Orthorhombic: *P2₁2₁2₁*, *P2₁/n 2₁/m 2₁/a* (*Pnma*), *C2/m 2/c 2₁/m* (*Cmcm*), *I2₁/b 2₁/c 2₁/a* (*Ibca*);

Trigonal: *P31m*, *P3m1*, *R3m*;

Hexagonal: *P6₃/m*, *P6₅22*, *P62m*, *P6₃/m 2/c 2/m* (*P6₃/mcm*);

Cubic: *I2₁3*, *I2₁/a3* (*Ia3*), *P4₃32*, *F43c*, *F4/m3 2/m* (*Fm3m*), *I4₁/a3 2/d* (*Ia3d*).

It is not possible to treat here the details of the derivation and the nomenclature of space groups. This topic requires a certain amount of practical acquaintance. The *International Tables*, Vol. A [*ITA* (2002)], contain complete listings and explanations of the 17 plane (two-dimensional) groups, the 230 space groups and the 32 crystallographic point groups. The so-called “subperiodic groups” (number of periodic dimensions lower than the total number of dimensions of the group), i.e., frieze, layer and rod groups, are presented in Vol. E (2002) of the *International Tables*. For textbooks, please see “Further reading” below.

Abstract

Crystal optics describes the light in anisotropic media when the optical response depends on the direction of propagation and polarization of the light beam, i.e. the refractive index may vary with direction. The optical anisotropy leads to the fundamental phenomenon of double refraction (birefringence) that has found a numerous applications optical engineering. In this chapter, we briefly discuss how the optical anisotropy can manifest itself in the light propagation and introduce basic devices to control light polarization.

Key points

- Causality principle and response function
- Constitutive equation and dielectric tensor
- Light wave propagation in anisotropic transparent medium
- Wave surface and ray surface in uniaxial and bi-axial crystals
- Wave plates and other devices to control polarization of the light beam

Introduction

Crystal optics describes the optical phenomena in anisotropic media when light waves may behave differently depending on direction propagation and polarization. This branch of optics is named after natural crystals that are used in optical devices for many years. The crystal optics techniques and approaches can also be employed to describe light propagation in non-crystalline bulk media (e.g., in an isotropic liquid) when static external fields induce optical anisotropy or in artificial structures, which can be created by recent advances in material science.

Conventionally, the crystal optics refers the light propagation in the transparent dielectric crystals leaving behind the dramatic enrichment of the propagation phenomena in the vicinity of the absorption resonances where the frequency and spatial dispersion may play decisive roles. Also, the crystal optics usually addresses the linear optical phenomena, which are governed by the second-rank tensor of the linear optical susceptibility. However, it is worth noting that the nonlinear optical phenomena, which arise due to dependence of the light propagation effects on the light wave amplitude and are governed by the higher-rank tensors of nonlinear susceptibility, are much more sensitive to the crystal symmetry. Nevertheless, the core part of the crystal optics has “crystallized” in pre-laser era and these intensity-dependent effects are studied in the framework of nonlinear rather than crystal optics. In this article, major effects in light propagation in anisotropic nonmagnetic media are discussed.

Maxwell equations

If the relative magnetic permeability of the medium is equal to 1 and no free electric charges and currents are present, the spatial and temporal evolution of the electric field $\mathcal{E}$, magnetic induction $\mathcal{B}$ and electric displacement $\mathcal{D}$ is determined by the Maxwell equations:

$$\operatorname{div} \mathcal{D} = 0$$

$$\begin{aligned}
\operatorname{div} \mathbf{B} &= 0 \\
\operatorname{curl} \mathbf{E} &= -\frac{1}{c} \frac{\partial \mathbf{B}}{\partial t} \\
\operatorname{curl} \mathbf{B} &= \frac{1}{c} \frac{\partial \mathbf{D}}{\partial t}
\end{aligned} \tag{1}$$

In the plane monochromatic wave with frequency ω and wave vector $\mathbf{k}$ that propagates in such a medium,

$$\begin{aligned}
\mathbf{E}(t, \mathbf{r}) &= E e^{-i\omega t + i\mathbf{k}\mathbf{r}} + E^* e^{i\omega t - i\mathbf{k}\mathbf{r}} \\
\mathbf{B}(t, \mathbf{r}) &= B e^{-i\omega t + i\mathbf{k}\mathbf{r}} + B^* e^{i\omega t - i\mathbf{k}\mathbf{r}} \\
\mathbf{D}(t, \mathbf{r}) &= D e^{-i\omega t + i\mathbf{k}\mathbf{r}} + D^* e^{i\omega t - i\mathbf{k}\mathbf{r}}
\end{aligned} \tag{2}$$

where the vectors E , B , D , and $\mathbf{k}$ are perpendicular to one another:

$$\begin{aligned}
\mathbf{k} \cdot \mathbf{D} &= 0 \\
\mathbf{k} \cdot \mathbf{B} &= 0 \\
\mathbf{k} \times \mathbf{E} &= \frac{\omega}{c} \mathbf{B} \\
\mathbf{k} \times \mathbf{B} &= -\frac{\omega}{c} \mathbf{D}
\end{aligned} \tag{3}$$

However, vectors E and D are not necessarily collinear. The plane containing vectors D and B (and perpendicular to the wave vector $\mathbf{k}$) is called the wave front plane, while those containing pair $\mathbf{k}$, B and $\mathbf{k}$, D are called the polarization plane and vibration plane, respectively. The plane containing orthogonal vectors E and B is perpendicular to the energy flux vector $\mathbf{S} = (c/4\pi) \langle [\mathbf{E} \times \mathbf{B}] \rangle$, where angular brackets stand for averaging over the wave period $T = 2\pi/\omega$, the direction of the ray propagation in the medium (see Fig. 1). It is worth noting that $\mathbf{S}$ is not necessarily parallel to the wave vector $\mathbf{k}$.

One can observe from (1) that the number of variables in Maxwell's equations is greater than the number of equations, an additional relationship (constitutive equation) is needed between electric displacement $\mathbf{D}$ and the wave fields. However, since $\mathbf{E}$ and $\mathbf{B}$ in nonmagnetic media are related by the third Maxwell equation in (1), this constitutive equation, which should account for the material properties of the medium, can be reduced down to functional relationship between electric displacement $\mathbf{D}$ and electric field strength $\mathbf{E}$.

It is worth noting that deriving the constitutive equation, i.e. finding the relationship between $\mathbf{D}$ and $\mathbf{E}$ in particular medium, is beyond the scope of electrodynamics and implies solving the light-matter interaction problem in the microscale (Landau and Lifshitz, 1984). Conventional approach involves quantum mechanical techniques that allow one to describe interaction of the electronic ensemble of particular medium with electromagnetic field. However, in order to solve the macroscopic problem of the propagation of the light wave it is often sufficient to consider restrictions that properties of the medium (e.g. its spatial symmetry) impose on the constitutive equation. We will see below that in crystal optics, such an approach enables transparent and consistent description of the light propagation by introducing uniaxial and bi-axial crystals.

Constitutive equation in anisotropic medium

Constitutive equation of the medium must obey the causality principle that ensures retrospective relationship between $\mathbf{D}$ and $\mathbf{E}$ is determined by the preceding electric field, but not by the future one. Similarly, the displacement is not necessarily local, that is, it could depend on the electric field not only at the point of observation, but also in some vicinity around it. With account for the causality and nonlocality, the constitutive equation for linear optics can be presented in the following form (Landau and Lifshitz, 1984):

Fig. 1 Mutual orientation of vectors $\mathbf{E}$, $\mathbf{B}$, $\mathbf{D}$, $\mathbf{k}$, and $\mathbf{S}$ in the anisotropic medium. Reproduced from Lyashenko DA and Svirko YuP (2005) Crystal optics. In: Encyclopedia of Condensed Matter Physics, 1st edn. Elsevier, 283–289.

$$\mathcal{D}_i(t, \mathbf{r}) = \sum_{j=x,y,z} \int_{-\infty}^t dt_1 \int_V d\mathbf{r}_1 \psi_{ij}(t - t_1, \mathbf{r} - \mathbf{r}_1) \mathcal{E}_j(t_1 \mathbf{r}_1) \quad (4)$$

Here, the subscripts label the Cartesian axes x, y, z of the laboratory frame, $\psi_{ij}(t - t_1, \mathbf{r} - \mathbf{r}_1)$ is the response function that describes the contribution into displacement at point $\mathbf{r}$ and time t resulting from the finite electric field at point $\mathbf{r}_1$ at time t_1 . Since $\mathcal{D}$ and $\mathcal{E}$ are vector quantities, the response function is tensorial by nature and relates projections of the displacement and electric field in the laboratory Cartesian frame. The properties of the response function are determined by the mechanism of the optical response in the medium and the medium symmetry. If the optical response is instantaneous, $\psi_{ij}(t - t_1, \mathbf{r} - \mathbf{r}_1) \propto \delta(t - t_1)$, the displacement at the moment t is given by the electric field at the same moment of time. If the displacement in a particular point $\mathbf{r}$ only depends on electric field strength at this location, $\psi_{ij}(t - t_1, \mathbf{r} - \mathbf{r}_1) \propto \delta(\mathbf{r} - \mathbf{r}_1)$. Since the optical properties originate from the response of the electron ensemble on the light field, the response function would normally have a maximum at $\mathbf{r} = \mathbf{r}_1$ and diminish for $|\mathbf{r} - \mathbf{r}_1| > a$, where a is the typical size of the atom or molecule. In crystals, the effects of the spatial dispersion are often associated with excitation of quasiparticles such as excitons, which may have effective radii of up to hundreds of angstroms.

The constitutive equation can be reduced to more familiar form if one considers propagation of a monochromatic wave with frequency ω and wave vector $\mathbf{k}$ (2):

$$D_i = \sum_{j=x,y,z} \varepsilon_{ij}(\omega, \mathbf{k}) E_j \quad (5)$$

where

$$\varepsilon_{ij}(\omega, \mathbf{k}) = \int_0^\infty d\tau \int_V d\mathbf{r} \psi_{ij}(\tau, \mathbf{r}) e^{i\omega\tau - i\mathbf{k}\mathbf{r}} \quad (6)$$

is the dielectric tensor that governs the propagation of the electromagnetic waves in the medium.

In the following, the spatial dispersion effects (Agranovich and Ginzburg, 1984) (i.e., the dependence of the dielectric tensor on the wave vector), which in the most cases result in a minor correction in the wave propagation in anisotropic media, are ignored. However, if the spatial dispersion is the only source of the optical anisotropy (e.g., circular birefringence in chiral liquids), it should be taken into account to describe phenomena of the optical activity and circular dichroism.

Dielectric tensor is symmetric with respect to permutation of its indices, $\varepsilon_{ij}(\omega, \mathbf{k}) = \varepsilon_{ji}(\omega, -\mathbf{k})$. This fundamental symmetry relation arises from the Onsager principle of symmetry of kinetic coefficients (Landau and Lifshitz, 1984) and holds in nonmagnetic media at thermal equilibrium. Another important property of the dielectric tensor is its Hermiticity that is, $\varepsilon_{ij}(\omega, \mathbf{k}) = \varepsilon_{ji}^*(\omega, \mathbf{k})$ in the frequency region where the absorption losses are negligible. Correspondingly, the energy dissipation rate when a light wave at frequency ω and wave vector $\mathbf{k}$ propagates in the medium is given by non-Hermitian part of the dielectric tensor:

$$Q = \frac{i\omega}{16c} \sum_{i,j=x,y,z} \left(\varepsilon_{ij}^*(\omega, \mathbf{k}) - \varepsilon_{ji}(\omega, \mathbf{k}) \right) E_i E_j^* \quad (7)$$

In the transparent medium without spatial dispersion the dielectric tensor is real, $\varepsilon_{ij}(\omega) = \varepsilon_{ji}^*(\omega)$ (Landau and Lifshitz, 1984), and, therefore, there exists a Cartesian frame in which it can be presented in the diagonal form:

$$\varepsilon_{ij} = \begin{pmatrix} \varepsilon_1 & 0 & 0 \\ 0 & \varepsilon_2 & 0 \\ 0 & 0 & \varepsilon_3 \end{pmatrix} \quad (8)$$

$\varepsilon_1, \varepsilon_2$ and ε_3 are called the principal dielectric constants. The coordinate axes of this system are called principal dielectric axes of the crystal. In this coordinate frame, the constitutive Eq. (5) reduces down to $D_x = \varepsilon_1 E_x, D_y = \varepsilon_2 E_y, D_z = \varepsilon_3 E_z$, that is, displacement and electric field are not parallel one another unless $\mathbf{E}$ coincides with one of the principal axes or principal dielectric constants are equal.

If the optical response is not instantaneous, the dielectric tensor depends on the frequency, and, therefore, both orientation of the principal axes and magnitude of the principal dielectric constants may vary with frequency (Patrini and Guizzetti, 2022). On the other hand, crystal symmetry imposes restrictions on the structure of the dielectric tensor and, therefore, on the number of nonequal principal dielectric constants (Ivchenko, 2022; La Rocca, 2022). The competition between symmetry restrictions and frequency (also referred to as color) dispersion allows one to introduce three distinct groups in the optical classification of the crystals (Lovett, 2017).

In cubic crystals, three crystallographically equivalent, mutually orthogonal directions may be chosen. In crystals of cubic system, principal dielectric constants are equal, $\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = \varepsilon$. Therefore, the constitutive equation in cubic crystals is the same as that in isotropic medium, $\mathbf{D} = \varepsilon \mathbf{E}$, that is, cubic crystals are optically isotropic. In these crystals, the frequency dispersion may change only the magnitude of the dielectric constant.

In crystals of trigonal, tetragonal, and hexagonal systems, the plain containing two equivalent perpendicular directions is perpendicular to the three-, four-, or sixfold rotation axis, respectively. Conventionally, this direction is chosen along the third principal axis. In these crystals, which are called uniaxial, relationship $\varepsilon_1 = \varepsilon_2 \neq \varepsilon_3$ holds at all frequencies.

In crystals of orthorhombic, monoclinic, and triclinic systems, no two equivalent directions can be chosen. These crystals in which $\varepsilon_1 \neq \varepsilon_2 \neq \varepsilon_3$, are called biaxial. In the crystals belonging to the orthorhombic system, the directions of the principal axes are fixed and coincide with twofold rotation axes and/or symmetry planes. This ensures their independence from the wave frequency. This situation changes for crystals of monoclinic system, in which the only twofold rotation axis exists, and correspondingly, orientation of just one principal axis does not show color dispersion. In the crystals of the triclinic system, both directions of principal axes and magnitudes of the principal dielectric indices may change with frequency.

Fresnel equation, wave vector surface, and ray surface

Maxwell Eqs. (3) allow one to arrive at the following equation for the amplitude of the displacement D when the light wave with frequency ω and wave vector k that propagates in the medium:

$$\frac{\omega^2}{c^2}D = [k \times [E \times k]] = k^2 E - (k \cdot E)k \quad (9)$$

By using constitutive Eq. (5) one can arrive at three linear homogeneous equations for the Cartesian components of electric field in the principal crystal frame:

$$\begin{aligned} \left(k_y^2 + k_z^2 - \frac{\omega^2}{c^2}\varepsilon_1\right)E_x - k_x k_y E_y - k_x k_z E_z &= 0 \\ -k_y k_x E_x + \left(k_x^2 + k_z^2 - \frac{\omega^2}{c^2}\varepsilon_2\right)E_y - k_y k_z E_z &= 0 \\ -k_z k_x E_x - k_z k_y E_y + \left(k_x^2 + k_y^2 - \frac{\omega^2}{c^2}\varepsilon_3\right)E_z &= 0 \end{aligned} \quad (10)$$

The compatibility condition for these equations is that the relevant determinant should vanish. This condition gives the so-called Fresnel's equation that defines the frequency dependence of the wave vector (or dispersion relation). By introducing vector $n = (c/\omega)k$ along direction of propagation and effective refractive index $n = \sqrt{n_x^2 + n_y^2 + n_z^2}$, the Fresnel equation is conventionally presented in the following form:

$$n^2(\varepsilon_1 n_1^2 + \varepsilon_2 n_2^2 + \varepsilon_3 n_3^2) - [n_1^2 \varepsilon_1(\varepsilon_2 + \varepsilon_3) + n_2^2 \varepsilon_2(\varepsilon_1 + \varepsilon_3) + n_3^2 \varepsilon_3(\varepsilon_1 + \varepsilon_2)] + \varepsilon_1 \varepsilon_2 \varepsilon_3 = 0 \quad (11)$$

When the direction of propagation is given, solution of the Eq. (11) gives two different magnitudes of the effective refractive index. Fresnel's equation in coordinates $\{n_1, n_2, n_3\}$ defines the so-called wave vector surface.

Normal to the wave vector surface gives the direction of the energy propagation (Poynting vector) in the medium. Usually, it is described by so-called ray vector s , which is introduced by condition $(ns) = 1$. Since the Poynting vector is perpendicular to E and B , one can readily arrive at

$$\begin{aligned} s \times B &= -E \\ s \times D &= B \end{aligned} \quad (12)$$

By replacing E with D and k with $-(\omega/c)s$ and vice versa in (3) one may arrive at (12). This corresponds to the rule of duality in the crystal optics. According to this rule, an equation valid for vectors E , n , and tensor ε_{ij} is also valid if these variables are replaced with D , s , and tensor ε_{ij}^{-1} , respectively. For example, from Fresnel's equation (11) one can obtain the equation which defines the ray vector surface:

$$s^2(\varepsilon_3 \varepsilon_2 s_1^2 + \varepsilon_1 \varepsilon_3 s_2^2 + \varepsilon_1 \varepsilon_2 s_3^2) - [s_1^2(\varepsilon_2 + \varepsilon_3) + s_2^2(\varepsilon_1 + \varepsilon_3) + s_3^2(\varepsilon_1 + \varepsilon_2)] + 1 = 0 \quad (13)$$

One can observe that when the direction of s is given, two rays with two different wave vectors can propagate in the crystal.

The above analysis can be visualized by means of simple geometrical constructions. One may draw the ellipsoid that corresponds to the tensor ε_{ij}^{-1} with semiaxes equal to the square roots of the principal dielectric constants. This equation is called ellipsoid of wave normals (also known as the index ellipsoid), and in the Cartesian frame with principal dielectric axes, it is described by the following equation:

$$\frac{x^2}{\varepsilon_1} + \frac{y^2}{\varepsilon_2} + \frac{z^2}{\varepsilon_3} = 1 \quad (14)$$

If the ellipsoid is cut by a plane which is orthogonal to the vector n , the intersection of the plane with the ellipsoid will be an ellipse (see Fig. 2). The length of its axes determines the two values of the effective refractive index, while the axes determine the directions of the relevant vector D . It is necessary to notice that unit vectors in these two directions and unite vector along n form Cartesian basis.

In order to find orientation of the electric field in the medium, the ellipsoid that corresponds to the tensor (8) with semiaxes equal to the square roots of the inverse principal dielectric constants (the Fresnel or ray ellipsoid) is considered:

$$\varepsilon_1 x^2 + \varepsilon_2 y^2 + \varepsilon_3 z^2 = 1 \quad (15)$$

If the ellipsoid is cut by a plane with normal s , the intersection of the plane with ellipsoid will be an ellipse, whose axes determine the two values of effective refractive index and orientation of the relevant vector E .

Optical properties of uniaxial crystals

In the uniaxial crystals, two principal dielectric constants are equal to one another ($\varepsilon_1 = \varepsilon_2 = \varepsilon_\perp$, $\varepsilon_3 = \varepsilon_\parallel$). This reduces the Fresnel equation (11) down to the product of two factors:

$$(n^2 - \varepsilon_\perp)[\varepsilon_\parallel n_3^2 + \varepsilon_\perp(n_1^2 + n_2^2) - \varepsilon_\parallel \varepsilon_\perp] = 0 \quad (16)$$

Fig. 2 Ellipsoid of wave normals. The normal to the wave vector section of the ellipsoid is ellipse (shaded). The lengths of its semi-axes determine the values of refractive index, while the directions of these orthogonal axes give the directions of oscillations, i.e. transverse components D_1 and D_2 of electric displacement vector. The sphere with radius equal to $\sqrt{\epsilon_{\perp}}$ lies inside the spheroid with main semi-axes $\sqrt{\epsilon_{\perp}}$ and $\sqrt{\epsilon_{\parallel}}$. Reproduced from Lyashenko DA and Svirko YuP (2005) Crystal optics. In: Encyclopedia of Condensed Matter Physics, 1st edn. Elsevier, 283–289.

This implies that the wave vector surface for uniaxial crystals consists of two separate surfaces, a sphere and spheroid, which touch one another at opposite poles on the n_3 -axis. Depending on the sign of $\epsilon_{\perp} - \epsilon_{\parallel}$ the crystal is said to be a negative or a positive uniaxial crystal (the sphere lies outside or inside the spheroid, respectively; see Fig. 3).

Correspondingly, there may exist two types of waves that propagate along a given direction in a uniaxial crystal. These waves are called ordinary and extraordinary waves having the following refractive indices, respectively:

$$n_o = \sqrt{\epsilon_{\perp}}$$

$$n_e = \sqrt{\frac{\epsilon_{\perp}\epsilon_{\parallel}}{\epsilon_{\perp}\sin^2\theta + \epsilon_{\parallel}\cos^2\theta}} \quad (17)$$

where θ is the angle between the optical axis (the principal axis “3”) and the wave normal. Two refractive indices are equal only at $\theta = 0$ when the wave normal coincides with the optical axis.

The ray surface can be found by replacing $\mathbf{n}$ with $\mathbf{s}$ and $\epsilon_{\perp}, \epsilon_{\parallel}$ with $\epsilon_{\perp}^{-1}, \epsilon_{\parallel}^{-1}$ in (16). For the ordinary wave, the directions of the wave vector and ray vector are the same, that is, with respect of ordinary waves the crystal behaves like an isotropic medium. For the extraordinary wave, the directions of the ray vector and wave vector do not coincide; however, they lie in the plane containing the wave vector and optical axis. This plane is called the principal plane. The angle θ' between the ray vector of the extraordinary wave and the crystal axes is given by the following equation: $\tan\theta' = (\epsilon_{\perp}/\epsilon_{\parallel}) \tan\theta$.

Since the four vectors E , D , s , and n always lie in the same plane, the extraordinary wave is polarized so that vector E lies in the principal plane. Therefore, in the ordinary wave, vector E lies in the plane, which is perpendicular to the principal one.

Optical properties of biaxial crystals

In biaxial crystals, the three principal values of the tensor are all different, that is, wave normally becomes ellipsoid rather than spheroid as in uniaxial crystals. The direction of principal axes may, in biaxial crystals, depend on frequency. The Fresnel surface can be obtained by solving Eq. (11). In the case of $\varepsilon_1 < \varepsilon_2 < \varepsilon_3$, the shape of one octant of the wave vector surface is shown in Fig. 4.

The singular point of self-intersection (there are four such points, one in each quadrant) gives the direction of the optical axes (referred as binormals) of the crystal. The dashed line in Fig. 4 passes through two opposite singular points and is at the following angle to the "3"-axis:

$$\tan \beta = \sqrt{\frac{\varepsilon_3(\varepsilon_2 - \varepsilon_1)}{\varepsilon_1(\varepsilon_3 - \varepsilon_2)}} \quad (18)$$

The directions of the optical axes are evidently the only ones for which the wave vector has only one magnitude.

The properties of the ray surface are entirely similar to those of the wave surface. The directions of optical ray axes (referred to as bi-radials) can be derived from (19) by replacing $\varepsilon_{1,2,3}$ with $\varepsilon_{1,2,3}^{-1}$:

$$\tan \gamma = \sqrt{\frac{\varepsilon_2 - \varepsilon_1}{\varepsilon_3 - \varepsilon_2}} \quad (19)$$

The directions of the wave vector and the ray vector are the same only for light propagating along one of the principal axes.

Near a singular point, the inner and outer parts of the wave vector surface are cones with a common vertex and, therefore, the direction of the normal to the surface becomes indeterminate. This implies that the wave vector along the binormal corresponds to an infinity of ray vectors, whose directions occupy a certain conical surface, called the cone of internal conical refraction. Similar results hold for the wave vectors corresponding to a given ray vector. The ray vectors along the biradial correspond to infinite number of wave vectors, whose directions occupy the cone of external conical refraction (Landau and Lifshitz, 1984).

In observations of the internal conical refraction, one can use a crystal plate cut perpendicular to the binormal. When monochromatic light wave incidents normally on one of the crystal faces, the wave vector of the transmitted wave is parallel to the binormal and so the rays are on the cone of internal refraction. Therefore, a collimated light beam that enters the crystal spreads out into a hollow cone emerging from the crystal as a hollow light cylinder.

In order to observe the external conical refraction, the crystal plate must be cut perpendicular to the biradial, and small apertures should be placed in exactly opposite positions on both crystal facets. When the first aperture is illuminated by a focused beam, only rays that propagate along the biradial can reach the second aperture. Therefore, the relevant wave vectors occupy the cone of the external conical refraction. It is worth noting, however, that the cone of light emerging from the crystal does not exactly coincide with the cone of external refraction because of the refraction on the crystal-vacuum interface.

Fig. 4 One octant of the Fresnel surface of a biaxial crystal with $\varepsilon_1 < \varepsilon_2 < \varepsilon_3$. Dash line shows the optical axis (binormal) of the crystal. One can observe that section of the Fresnel surface by the plane normal to one of the coordinate axes consists of ellipse and circle. In the plane $\{n_1, n_2\}$, ellipse with semi-axes $\sqrt{\varepsilon_1}$ and $\sqrt{\varepsilon_2}$ lies inside the circle with radius $\sqrt{\varepsilon_3}$, while in the plane $\{n_2, n_3\}$, the circle with radius $\sqrt{\varepsilon_1}$ lies inside the ellipse with semi-axes $\sqrt{\varepsilon_2}$ and $\sqrt{\varepsilon_3}$. In the plane $\{n_1, n_3\}$, the ellipse with semi-axes $\sqrt{\varepsilon_1}$ and $\sqrt{\varepsilon_3}$ and crosses the circle with radius $\sqrt{\varepsilon_2}$. Reproduced from Lyashenko DA and Svirko YuP (2005) Crystal optics. In: Encyclopedia of Condensed Matter Physics, 1st edn. Elsevier, 283–289.

Polarization devices based on the crystal optics

Since in the crystal two linear polarized waves with different wave vectors are allowed along a given direction, one can observe double refraction or birefringence at the vacuum–crystal interface. That is, an arbitrary polarized light beam entering an anisotropic crystal is divided into two beams with orthogonal linear polarizations. The direction of propagation of the beams is determined by the orientation of the incident wave vector with respect to the principal crystal axes and does not necessarily lie in the incident plane. These properties of the vacuum–crystal interface have enabled one to develop various devices to control and to investigate the polarization properties of the light. The polarization devices belonging to two most common types are discussed below. These are polarizers that produce linearly polarized light by splitting an elliptically polarized beam into two linearly polarized ones, and retarders that control the ellipticity of the light beam by changing the phase difference between its orthogonally polarized components (Bain, 2019).

The Nicol prism was invented in the nineteenth century and consists of a natural rhombic crystal of calcite, which is cut into two parts along a diagonal plane, and joined together again with Canada balsam (see Fig. 5). For a given angle of incidence, at the vacuum–crystal interface a light beam splits into ordinary and extraordinary rays with effective refractive indices $n_o = 1.6584$ and $n_e = 1.4864$, respectively. Since the refractive index of the Canada balsam $n_{balsam} = 1.5260$ satisfies the condition $n_e < n_{balsam} < n_o$, the ordinary ray undergoes total reflection at the Canada balsam joint while the extraordinary ray passes through. Therefore, the Nicol prism allows one to achieve linear polarization with practically no lateral displacement of the incident light beam. It is necessary to notice that a number of polarizing prisms (e.g., Glan–Foucault polarizer that employs total internal reflection similar to the Nicol prism and Wollaston prism that produce two orthogonally polarized output beams) have been devised.

The difference in the phase velocity of the ordinary and extraordinary waves in the birefringent crystal enables one to achieve a desired phase difference between them by changing the crystal thickness and/or the relevant refractive indices. Since the directions of vibrations in these waves are mutually orthogonal, the total phase difference accumulated between them determines polarization of the transmitted light. Such devices are called compensators because they enable to compensate the phase difference between orthogonal components of the elliptically polarized light wave. It is noticed here that these devices may also be referred to as retarders, because they introduce a finite retardation of one component with respect to another.

A compensator is usually made from a parallel plate of birefringent crystal that is cut so that the optic plate. At the vacuum–crystal interface ($z = 0$), the input wave at normal incidence divides into ordinary and extraordinary ones that propagate with phase velocities $v_o = c/n_o$ and $v_e = c/n_e$, respectively, and linearly orthogonally polarized. If the amplitudes of the orthogonal components of the light field in Eq. (1) at $z = 0$ are equal to E_x and E_y , respectively, those of the light waves emerging from the plate are given by $E_x \exp \{2\pi i n_o d / \lambda\}$ and $E_y \exp \{2\pi i n_e d / \lambda\}$, where λ is the wavelength in the vacuum. Therefore, the phase difference, which plate introduces between ordinary and extraordinary waves, is given by the following equation:

$$\Delta\varphi = \frac{2\pi d}{\lambda} (n_o - n_e) \quad (20)$$

The quarter-wave plate has a thickness of $d = \lambda/4 |n_o - n_e|$ and introduces a phase difference $\Delta\phi = \pm \pi/2$ to the transmitted wave. This wave plate transforms linearly polarized wave into circularly polarized one and vice versa. In order to obtain circularly polarized wave from linearly polarized, the optical axis of the plate is oriented at 45° to the incident polarization azimuth so that $E_x(z=0) = E_y(z=0)$. In such a case, the amplitudes of the transmitted ordinary and extraordinary polarized waves remain equal in magnitude. However, they acquire the $\pm\pi/2$ phase shift, that is, $E_x(z=0) = E_y(z=0)$ and $E_x(z=d) = \pm i E_y(z=d)$. This implies that the wave becomes left- or right-circular polarized depending on the relationship between n_o and n_e .

The wave plate with thickness of $d = \lambda/2 |n_o - n_e|$ is called the half-wave-plate, which allows one to rotate the polarization azimuth by 90° . If the optical axis of the plate is oriented at 45° to the incident polarization azimuth (that is, $E_x(z=0) = E_y(z=0)$), in the transmitted wave, the extraordinary polarized components acquire the π phase shift, that is, $E_x(z=d) = E_x(z=0)$ while $E_y(z=d) = -E_y(z=0)$. One can readily find that this corresponds to the rotation of the polarization azimuth by 90° or to the transformation of the left circular polarized beam to the right circular polarized one.

Fig. 5 The Nicol prism produces the light beam polarized in the plane of the picture (e-beam). The orthogonally polarized o-beam undergoes total internal reflection on the calcite–Canada balsam interface. Reproduced from Lyashenko DA and Svirko YuP (2005) Crystal optics. In: Encyclopedia of Condensed Matter Physics, 1st edn. Elsevier, 283–289.

The frequency dispersion results in color sensitivity of the wave plates. In order to achieve compensation of the phase shift for any wavelength, devices based on the combination of edges are used. The most common examples are the Babinet and Soleil compensators (Bain, 2019).

Conclusion

Crystal optics is a well documented discipline describing materials having optical properties depending on the direction in which the light is propagating. These are anisotropic crystals in the first instance. The term crystal optics has been coined in pre-laser era, i.e. it studies only linear optical phenomena in crystalline media including birefringence and its application to control the polarization of light. However, the nonlinear-optical, electro-optical and magneto-optical phenomena, which are widely used to control light beams, are essentially rely on the fundamental laws of crystal optics. In this article, we address the optical properties of bulk materials leaving behind rapidly developing optics of nanostructures that may also possess properties attractive for both fundamental principles and applications.

Starting from Maxwell's equations that describe the evolution of the electromagnetic field in the medium, we introduce phenomenological constitutive equation, which allows one to introduce the dielectric tensor and to address the propagation of light in uniaxial and bi-axial crystals. We introduce the general approach to the description of the light propagation in crystals using the wave and ray normals, and consider how the birefringent crystals can be employed to control the polarization of light.

Abstract

Holography was discovered in 1948 by Denis Gabor and its development started in the beginning of the 1960s with the invention of the laser. This article presents the basis of the holographic principles, and then the most commonly used optical setup to record and reconstruct holograms. A short review of the different recording materials and the applications follows. The computer-generated holograms and the diffractive optical elements with their computation algorithms and their applications are then described.

The last sections are dedicated to two recent fields of holography: the digital holography and the artificial surfaces.

Key points

- Optical holography: principle, optical recording set-up, application
- Computer generated holograms, diffractive optical elements: algorithms and applications
- Digital holography: principle and applications
- Artificial surfaces

Introduction

Holography was discovered in 1948 by Denis Gabor who proposed to use this technique to improve the resolution in electron microscopy (Gabor, 1948). Denis Gabor received the Nobel prize for this work in 1971. The word holography comes from Greek words meaning “total recording,” and it is a technique for “wave front reconstruction” where both amplitude and phase of a wave front are recorded. The development of holography started in the beginning of the 1960s when coherent light sources became available with the invention of the laser. In 1962, E. Leith and J. Upatnieks made a major breakthrough with the invention of the off-axis reference beam optical holography (Leith and Upatnieks, 1962). A few years later, in 1967, A. Lohmann presented the first computer-generated hologram (Lohmann and Paris, 1967). The most spectacular application is the three-dimensional (3D)

imaging, but there are now numerous applications where holography is even more useful and important for nondestructive testing, security, data storage, coherent wavefront shaping or for new optical elements for image display and projection in augmented reality, etc.

This article presents the basis of the holographic principles, and then the most commonly used optical setup to record and reconstruct holograms. A short review of the different recording materials and the applications follows. The following sections are dedicated to computer-generated holography and diffractive optics and finally the sections are devoted to the recent fields of digital holography and of artificial surfaces.

Principle of holography

The purpose of holography is a wave front reconstruction (Collier et al., 1971; Hariharan, 1984; Hecht, 2002; Iizuka, 1987; Saxby, 1988). It is a two-step process, which involves first, the recording of the amplitude and phase of the wave front, and second, its reconstruction. All the available recording materials (photographic plates, photopolymers, photorefractive crystals, etc.) or recording devices (CCD or CMOS cameras) are only sensitive to the intensity of the wave front, and therefore all the phase information is lost. Since the interferences between two coherent waves reflect their phase differences, the idea of recording the whole wave is to record the intensity of the interferences between the desired wave front (object beam) and a known reference wave (reference beam). This can be easily illustrated by the following equation when the O and R beams interfere with the same linear polarization:

$O(x, y)$ called the object beam, is the wave to be recorded:

$$O(x, y) = |O(x, y)| \exp j\Phi(x, y)$$

$R(x, y)$ called the reference beam is a known wave that interferes with the object beam:

$$R(x, y) = |R(x, y)| \exp j\Psi(x, y)$$

$I(x, y)$ is the intensity of the interference pattern between the object and reference beams (* indicates the complex conjugate), and using the simplified notations O and R , one obtains:

$$I(x, y) = |O + R|^2$$

$$I(x, y) = |O|^2 + |R|^2 + OR^* + O^*R$$

It is assumed that the recording medium is an ideal holographic material in which the amplitude transmittance $t(x, y)$ is proportional to the recorded intensity $I(x, y)$. To reconstruct the wave front, the hologram is illuminated by a wave identical to the reference beam and this is given by the following equation:

$$R(x, y)t(x, y) = |O|^2R + |R|^2R + O|R|^2 + O^*R^2$$

These last two terms of this development show that 3D imaging is possible since the complete amplitude and phase of the original wave front $O(x, y)$ is reconstructed. It can also be noted that due to the recording process, each point of the object contributes to the whole surface of the hologram. Therefore, even a partially illuminated hologram reconstructs the image of the whole object, but the quality of the image is affected due to a reduction of the spatial resolution and contribution of coherent speckle noise in the image plane.

Principal holographic setups

In the previous section, the basic principle of holography was presented and, in this section, the three principal setups that are used for optically recording and reconstructing holograms are detailed (Hariharan, 1984).

The in-line hologram

The in-line configuration shown in Fig. 1 is also named the Gabor hologram since D. Gabor first proposed this optical setup to demonstrate holography. The object is mostly transparent and may contain opaque particles. It is illuminated by a uniform coherent parallel beam and the transmitted wave is composed of two parts:

1. The wave directly transmitted by the object, noted as R , is constant and forms the reference.
2. The wave scattered by the particles, noted as O , and forms the object beam.

It is assumed that the intensity distribution $I(x, y)$ due to interference of O and R wave amplitudes is recorded on a photographic plate in early experiments, but now most commonly on 2D electronic sensors, whose transmittance $t(x, y)$ is proportional to the intensity and exhibits a constant offset t_0 . Then, one has the following relation:

$$t(x, y) = t_0 + kI(x, y)$$

where k is a constant including the exposure time and the slope of the recording material.

Fig. 1 Recording a Gabor hologram. From Ambs P, Huignard JP, and Loiseaux B (2016) *Holography, Reference Module in Materials Science and Materials Engineering*. Elsevier.

Fig. 2 Reconstructing a Gabor hologram. From Ambs P, Huignard JP, and Loiseaux B (2016) *Holography, Reference Module in Materials Science and Materials Engineering*. Elsevier.

To reconstruct the Gabor hologram, it is illuminated with a coherent parallel plane wave R (see Fig. 2), and the wave transmitted by the hologram is given by

$$Rt(x, y) = R (t_0 + k|R|^2) + kR|O|^2 + k|R|^2O + kR^2O^*$$

The three terms of the reconstruction are presented in Fig. 2. (1) $R(t_0 + k|R|^2 + k|O|^2)$ is the transmitted beam. (2) $k|R|^2O$ is the original object wave multiplied by a constant. It generates a reconstruction of the object located at its original position behind the hologram. It is a virtual image. (3) kR^2O^* is the complex conjugate of the original object. It generates a real image of the object in front of the hologram.

Application of the Gabor holograms

The main application of the Gabor holograms is in the particle analysis. In conventional imaging systems, the combination of a large depth of field with a high resolution is not possible. This bottleneck can be solved using a holographic recording that can store a high-resolution 3D image. The in-line hologram of the volume of moving particles is recorded using a triggered pulsed laser and the real 3D image can be analyzed by a conventional camera, which images the different planes of the volume. As an example of application, this setup was used to analyze the size and shape of droplets generated by injectors. Today, the in-line holography is typically an application of digital holography where the recording media, i.e. the holographic plate, is replaced by a high-resolution electronic camera. The reconstruction of the recorded hologram is then digitally computed through the calculation of the spatial 2D Fresnel or Fourier transform of the interferogram.

The off-axis hologram

With the Gabor hologram, the three reconstructed wave fronts are on the same axis and they cannot be spatially separated. To solve this problem, E. Leith and J. Upatnieks proposed in 1962 the off-axis recording setup (Leith and Upatnieks, 1962). In this case, the reference beam $R(x, y)$ and the object beam $O(x, y)$ are separated and interfering on the holographic plate under an angle α (see Fig. 3). The object beam and the off-axis plane wave reference beam are respectively expressed by

$$O(x, y) = |O(x, y)| \exp j\Phi(x, y)$$

$$R(x, y) = |R(x, y)| \exp j2\pi\zeta x$$

where $\zeta = \frac{\sin \alpha}{\lambda}$

Fig. 3 Recording an off-axis hologram. From Ambs P, Huignard JP, and Loiseaux B (2016) *Holography, Reference Module in Materials Science and Materials Engineering*. Elsevier.

As in previous relations $I(x, y) = |R + O|^2$ is the intensity of the interference fringes.

Following the above formalism, it is clear that when reconstructing this type of hologram with the off-axis reference beam as shown in Fig. 4, it generates two spatially separated waves $W_1(x, y)$ and $W_2(x, y)$, respectively expressed by

$$W_1(x, y) = k|R|^2 O$$

where $W_1(x, y)$ is the original object wave multiplied by a constant factor and generates a virtual image of the object and $W_2(x, y) = kR^2 O^* \exp(j4\pi\zeta x)$ is the complex conjugate of the original object wave and generates a conjugate real image.

The three waves R , W_1 , and W_2 are separated angularly and do not overlap as shown in the Gabor holograms. The off-axis setup is now the most common holographic recording configuration and it is used for reconstructing 3D images.

The Fourier hologram

In this case, the object is planar and the purpose is to record the amplitude and the phase of its Fourier transform (FT) (Goodman, 1968). The holographic technique is used to record this complex wave front. The hologram is formed by the interference pattern between the FT of the object $O(u, v)$ and a tilted wave that is the reference beam $R(u, v)$ (see Fig. 5)

Fig. 4 Reconstructing an off-axis hologram. From Ambs P, Huignard JP, and Loiseaux B (2016) *Holography, Reference Module in Materials Science and Materials Engineering*. Elsevier.

Fig. 5 Recording a Fourier hologram. From Ambs P, Huignard JP, and Loiseaux B (2016) *Holography, Reference Module in Materials Science and Materials Engineering*. Elsevier.

$$O(u, v) = FT[O(x, y)]$$

$$R(u, v) = \exp(j2\pi ua)$$

where a is a constant.

$I(u, v)$ is the intensity of the interferences between the object and the reference beams

$$I(u, v) = I + |O(u, v)|^2 + O(u, v) \exp(-j2\pi ua) + O^*(u, v) \exp(j2\pi ua)$$

For the reconstruction, the hologram is illuminated by a parallel plane wave (of amplitude unity to simplify) and the wave transmitted by the hologram is

$$U(u, v) = t_0 + kI(u, v)$$

The hologram is placed in the front focal plane of a lens (see Fig. 6) and therefore the wave in the focal plane is the FT of $U(u, v)$ where

Fig. 6 Reconstructing a Fourier hologram (A) the optical setup, and (B) the optical reconstruction of a Fourier hologram. From Ambs P, Huignard JP, and Loiseaux B (2016) *Holography, Reference Module in Materials Science and Materials Engineering*. Elsevier.

$$U(x, y) = FT[U(u, v)] = (t_0 + k)\delta(x, y) + kO(x, y) \otimes O(x, y) + kO(x - a, y) + kO^*(-x + a, -y)$$

where $\otimes$, represents the correlation operator. This diffraction pattern is composed by a central order plus two terms:

1. $kO(x - a, y)$ is the +1 diffraction order that represents the original object beam separated by a distance a from the central order, and
2. $kO^*(-x + a, -y)$ is the -1 diffraction order that represents the complex conjugate of the original object beam separated by a distance $-a$ from the central order.

These two images of the object transparency are real.

Fourier holograms are not designed for 3D imaging; they have more specific applications such as optical correlation for pattern recognition, high-capacity holographic data storage, 2D imaging, diffractive optical elements, and optical interconnections.

Speckle noise in holographic imaging

The image reconstruction from a hologram illuminated by a highly coherent laser source will suffer from noise, named speckle noise, which limits the image quality. The speckle arises from the coherent illumination from any scattering object surface. Its origin is due to the diffraction of the object surface micro reliefs making up the coherent complex addition and interference of elementary waves with random phases. From this process it thus results an apparent image granularity of high contrast on the image which degrades the image signal-to-noise ratio. This effect is specific to any coherent imaging technique with a lens or hologram, it does not happen in conventional incoherent light source imaging. The statistic of the speckle pattern has been firstly analyzed in detail by J. Goodman in reference (Goodman, 2015) thus leading to estimation of image quality through the calculation of the image variance intensity. In the case of image formation by a hologram, it is shown that the size of the elementary speckle grain is of the order of the diffraction spot of the image formation system, which in the case of hologram is of the order of $\delta = \lambda \frac{F}{H}$ where λ is the laser wavelength, F is the distance from hologram to image and H the size of the hologram aperture. This effect must be carefully considered in any applications of coherent imaging and detection.

Hologram characteristics and recording procedure

An important parameter of the holographic reconstruction is the diffraction efficiency. It is defined as the ratio between the light beam intensity of the desired reconstructed image and the intensity of the incident beam illuminated on the hologram during the reconstruction.

Depending on the recording material, the hologram can introduce an amplitude or a phase modulation. A spatial phase modulation is often preferred since the diffraction efficiency is higher and can reach hundred percent. If the recording material thickness is small compared to the fringe spacing, a thin grating is recorded and the Raman–Nath diffraction regime applies. The reconstruction produces several diffraction orders and the efficiency gets reduced. On the other hand, a thick volume hologram is recorded if the thickness of the recording material is large compared to the fringe spacing. In such a case, a 3D grating is obtained and the Bragg diffraction regime applies. The fundamental properties of these thin-thick amplitude or phase volume holograms are well described by the coupled wave model firstly published by H Kogelnik in the reference (Kogelnik, 1969; Brotherton-Ratcliffe, 2013). Phase volume holograms have two very attractive properties (Moharam and Gaylord, 1981): (1) when illuminated by the reference beam, it reconstructs only one beam due to perfect spatial phase matching, and a diffraction efficiency of 100% can be theoretically reached, and (2) angular multiplexing of holograms is possible due to spatial selectivity. In this case, the angle of incidence of the reference beam is different for each of these holograms, which are recorded in the same volume.

Each hologram is then addressed and reconstructed when illuminated by the reference beam with the corresponding incidence angle. It is also possible to multiplex holograms using different wavelengths. Holograms, which can be sequentially stored in the same volume location by varying the reference beam angle at each recording step, provide the capability of high-capacity data storage of digital pages of information (Coufal et al., 2000; Curtis et al., 2011).

Also, holograms recorded with the optical setup of Fig. 3 are of the transmission type. However, if a hologram can be recorded by two waves traveling in opposite directions and illuminating respectively the front face and the rear face of the recording medium, the fringes inside the recording medium will be parallel to its faces; this is a reflective type of hologram. In these conditions the reflective hologram also exhibits very interesting properties, in particular its Bragg spectral selectivity which is now commonly used in wavelength filtering applications reference (Kogelnik, 1969).

The requirements for optically recording holograms are imposed by the contrast and stability of the interference fringes. The illuminating laser source must be coherent with an adequate coherence length, and the optical setup is stable and isolated from the vibrations. Note that the coherence length of the laser source, given by the classical formula $l_c = \frac{\lambda^2}{\Delta\lambda}$ with λ the wavelength and $\Delta\lambda$ the wavelength bandwidth is an important parameter since it limits the optical path length difference between the Signal and reference wavefronts interfering on the detector. Ideally, the recording media must not only have a high spatial resolution, typically higher than 1000 lines per mm, but also a linear response, a sensitivity range which can match the available laser wavelengths and a low noise.

Most of the hologram recording materials are nonerasable, such as the commonly used materials listed below:

1. Silver halide emulsions have been used since the beginning of holography. After processing, the light intensity is then transformed into an amplitude modulation. However, it is possible to change this modulation into a phase modulation by bleaching the plate thus allowing a higher diffraction efficiency to be reached. The use of photographic emulsions implies a chemical wet processing. Silver halide emulsions fulfill most of the requirements for holographic recording media – they are relatively sensitive, have a large spectral response, and a high spatial resolution. Holographic emulsions were easily commercially available until all the large photographic material companies stopped their production several years ago. Now, only a few small companies are still producing very high resolution holographic plates.
2. Dichromated gelatin is sensitized by ammonium dichromate imbedded into the gelatin, and it produces large area phase holograms. It is a very good material for holography with high resolution ($>10,000$ lines per mm), a controlled large modulation of the refractive index ($\Delta n > 0.1$), low absorption, and scattering. The use of dichromated gelatin is mastered at the industrial level with well-controlled processes to achieve $\sim 100\%$ diffraction efficiency.
3. Photopolymers films are organic materials that transform the light intensity into a refractive index modulation through a photopolymerization process. This is a self-processing photochemical reaction and the hologram is recorded and fixed by illuminating the photopolymer, and no further processing is required. Of late, several companies have been selling their photopolymers which exhibit excellent characteristics for high-efficiency holographic components ($\Delta n > 5 \times 10^{-2}$) as suitable for several applications (Curtis and Psaltis, 1994; Loiseaux et al., 1996; Weitzel et al., 1997; Joubert et al., 2002).
4. Organic materials such as photoresists thin films on glass substrate which are well developed for microelectronic technologies can be used for holographic recording. The illuminating coherent light gives a relief modulation after wet development and thus records a thin transmission type relief hologram. Photoresists are now very well-established materials used for the fabrication of the masters and for replicating the holograms by embossing. This is a largely developed technology for security applications (Bjelkhagen, 2005).
5. Photopolymers like polymethyl methacrylate - PMMA are an interesting phase volume holographic recording material, in particular the materials including photoinitiators like Irgacure or phenanthrenequinone (PQ) doped PMMA. It is shown that Irgacure PMMA materials exhibit low shrinkage, very good stability and attractive potential qualities for high storage density by hologram multiplexing. Photochemical mechanisms in these types of photopolymers are now well analyzed and controlled. Meanwhile, the holographic characteristics with continuous wave or pulse exposure with visible green lasers have been published with efficiencies of 50% in mm thick materials. Irgacure PMMA also operate both in conventional or in polarization holography and thus benefit from the diffraction of an orthogonal direction of polarization. These materials now permit efficient phase volume holographic gratings and other types of diffractive components whose characteristics are well suited in laser and photonic applications (Steckman et al., 1998; Lin et al., 2009; Liu et al., 2017, 2019; Laux et al., 2007).
6. Holographic grating in glass: very efficient phase volume holographic gratings are also recorded in silicate glass doped with Cerium, Silver, and Fluorine. Grating recording is done in the UV, typically at a wavelength of 325 nm. UV exposure and thermal treatments photoinduce a localized index modulation due to material structural transformations and to local stresses in the glass volume (Photo Thermal Refractive Process). It thus results in the realization of several mm thick components of high optical quality, very good mechanical stability and very well suited for applications like spectral filtering, spectral combining of lasers, laser cavities mirrors, short pulse manipulation... (Mach et al., 2022; Glebov et al., 2002, 2014; Lumeau et al., 2009; Moser et al., 2008).
7. Erasable holographic materials are required for dynamic holography.
 - a. The most commonly used materials in this category are photorefractive crystals. In this class of materials, the phase volume holographic grating is due to a photoinduced space charge field which modulates the crystal refractive index through the electrooptic effect (Yeh, 1993; Günter and Huignard, 2007). The index modulation can be erased by illuminating the crystal with a uniform beam intensity. Most of the photorefractive crystals also exhibit a dark storage time constant. A significant effort of research is still being done to investigate the phenomena involved in efficient hologram recording in the visible and near infrared spectral range. Photorefractive crystals permit the recording of dynamic holograms with time constants varying from nanoseconds to several seconds, and consequently, the diffracted wave front is probed in real time. Moreover, due to the nonlinear optical behavior of the material, there is an energy redistribution between the two recording beams. In other words, a low-intensity object beam can be amplified through an energy transfer from the reference beam. This unique property of the photorefractive crystals, due to self-diffraction mechanisms, opens up its applications like parametric image amplification. Many other attractive applications can be realized based on the specific characteristics of photorefractive effects in a variety of crystals. Presently, the most important materials used in experiments are: LiNbO_3 iron doped; BaTiO_3 ; KnbO_3 ; $\text{Bi}_{12}(\text{Si, Ge, Ti})\text{O}_{20}$; for visible and GaAs; InP or CdTe for the near IR. Besides the spectral sensitivity, they differ in terms of speed, dark storage time, diffraction efficiency, and a two-wave mixing gain coefficient.
 - b. Several other types of nonlinear optical effects have also been used in experiments of dynamic holography, in particular:
 - The nonlinear two beam interaction (2WM) creating a dynamic phase hologram in the materials. The reference beam which interferes with a low intensity signal beam acts as a pump which transfers its amplitude to the signal which is then amplified. It thus results an exponential gain coefficient on the signal beam intensity. In another important configuration, the dynamic hologram is readout with a beam which is antiparallel to the reference beam (4WM) and in these conditions generates an amplified phase conjugate wave of the incident signal wave (phase conjugate mirror with gain). These

mechanisms are at the origin of attractive properties like coherent image amplification, amplified phase conjugation and self-induced multimode cavities. (Rajbenbach et al., 1984). Demonstrations and applications of these remarkable properties will require the choice of the most efficient type of nonlinear interaction among the above list of materials and physical mechanisms, also as function of the requirements on the material response time, laser wavelength and its operating mode CW or pulsed (Fisher, 1983)

- The optical Kerr effect in transparent media, Stimulated Brillouin Scattering, photorefraction in doped liquid crystal or polymers, thermal gratings, or free carriers holographic gratings in semiconductor crystals. . . Also the hybrid structure like the optically addressed liquid crystal light valve is of great interest in holographic experiments (Residori et al., 2009). It consists of a 5-50 μm thick liquid crystal film sandwiched between a photoconductive crystal $\text{Bi}_{12}(\text{Si, Ge, Ti})\text{O}_{20}$ or GaAs and a glass substrate with transparent electrodes. Under low applied voltage and low intensity incident fringe grating illumination, the device generates an efficient thin phase hologram due to a periodic reorientation of the liquid crystal molecules having a large birefringence. Another type of hybrid structure operating at video frame rate is in reference (Bortolozzo et al., 2015) using a CMOS detector, and an electrically addressed Liquid crystal SLM. CMOS camera and the SLM are symmetrically placed at 45 degrees from a 50% beam splitter and precisely imaged one onto each other. The holographic fringes are detected on the CMOS and video signal is transferred onto the Liquid crystal SLM which diffracts the holographic signal. Applications to dynamic interferometry of vibrating structures are demonstrated in ref. (Bortolozzo et al., 2015).

Applications of optical holography

Holography has a large range of applications although it is not as commonly used as it was expected to be in its early stages in the 1960s. Several applications are listed below:

1. Display is the most spectacular and public-oriented application of holography. Large transmissive and reflective holograms have been recorded, and 3D images with a large depth of field have been reconstructed. Different varieties have been developed, particularly in hologram reconstruction with white light, such as the rainbow or color holograms. For color imaging, three holograms of the object are recorded successively on the same plate by three lasers emitting blue, red, and green light respectively. The recording media must have a high resolution and a broad spectral sensitivity range. Such color reflective holograms reconstruct a 3D color object when illuminated by white light (Saxby, 1988).
2. Holography also has industrial applications in nondestructive testing, thanks to holographic interferometry (Smigielski, 1994). The purpose of classical interferometry is to compare two wave fronts, though most of the time one wave front is tested with a reference one. The principle of the double exposure holographic interferometry is, first, to record holographically the wave front coming from an object at rest. Second, some constraints or stress (mechanical, thermal, etc.) are applied to the object and the new wave front coming from the object is also recorded on the same support. When the resultant hologram is illuminated, it reconstructs the two wave fronts that interfere together and the resultant fringe pattern reveals the modifications of the object with a slight change in its shape. In particular, dynamic holography in photorefractive crystals is very well suited for these applications. As an example, the crystals permit realizing double exposure interferometry and when the object structure is vibrating at a given frequency, the photorefractive 2WM interaction operating in the time average recording mode, display in real time the vibration modes of the structures (Günter and Huignard, 2007; de Montmorillon et al., 1997; Kamshilin et al., 2009). These experiments based on dynamic holography are used in a diversity of industrial applications for metrology, non-destructive testing and vibrometry of structures. The functions of holographic interferometry are also performed most frequently with digital holographic techniques due to the availability of high-performance detector matrix and digital data processing (Schnars et al., 2015).
3. Holographic optical elements (HOEs) are also becoming an important industrial application. These elements are recorded optically, mainly on dichromated gelatin or in photopolymer and their purpose is to convert one wave front into another. One of the first industrial applications of HOEs is the head-up display that is used in airplanes and recently in cars (Teich et al., 2022). Holographic solutions are also one of the technologies used for waveguide combiners of smart glassed for augmented reality (AR), virtual reality (VR) or extended reality (XR) headsets (Kress and Chatterjee, 2021; Chang et al., 2020). HOEs can implement, even simultaneously, complex optical functions such as focusing, deflecting, multiplexing, spectral filtering, and active beam shaping (Mestre et al., 2007). Also, they are used in spectral pulse stretching and compression of lasers delivering ultrashort femto-second pulses (Loiseaux et al., 1996; Treacy, 1969; Maine et al., 1988; Mourou et al., 2015).
4. Holographic memories were studied in research laboratories, and an attempt to develop systems were considered by a few companies. The data pages are written as holograms into a thick layer of photopolymer coated onto a rotating disk (Coufal et al., 2000). The digital data can be recovered in parallel by reconstructing the holograms page-by-page. Therefore, a high data rate could be achieved and the recording medium would allow a very long archival lifetime. Few prototypes of holographic data storage systems were realized but actually impressive progress on the performances of electronic digital semiconductor memories surpass for the moment any other technological approach.
5. Since holograms are difficult to reproduce, they were used early as a security feature, on banknotes, for example. In this case, the original hologram is recorded optically on a photoresist and used to fabricate a master. The embossing of a sheet of a reflective

material produces the final hologram. Holographic solutions have been widely investigated for introducing anti-counterfeiting items both for biometric, banknotes or credit card document verification or for high-value product protection. For such applications both diffractive optical element (DOE) relief embossing and volume holography have been developed and are now commonly used. There are still ongoing research projects on this domain and the introduction of new technologies such as optical 3D printing by multi-photon polymerization (<http://www.phenomenonproject.eu/>) (Fagan, 1990; Bjelkhagen, 2005; Hilbert et al., 2020; Song et al., 2019).

6. Fiber Bragg Gratings (FBG) for telecommunications: UV illumination of silica glass around 244 nm permit to induce significant refractive index changes provided that appropriate methods of glass photosensitization are used. It was early recognized the important role of hydrogen treatments for enhancing the photosensitive response of silica-based glass, thus inducing index changes with high stability and as large as 10^{-3} . Research is still concerned to understand and to optimize the UV-induced index modulation, to minimize the sensitivity to changes of the environment, in particular when writing the gratings in a planar waveguide or in the core of a fiber. The Bragg grating photoinduced in low loss silica fibers is now a packaged technology fully developed in industry for applications in telecommunications and fiber sensors. They are a basic component for spectral filtering in dense wavelength optical communications networks (Kashyap, 2009; Poumellec, 1998; Niay et al., 1994; Chen et al., 2002; Brambilla et al., 1999; Groothoff et al., 2003).
7. The holographic techniques also apply in other domains than optical frequencies and are now proposed as essential to shape and process microwaves for radar systems and for analog or digital data transmissions in free space or over fiber links. High frequency microwave modulation of the optical laser carrier permit to attain very large bandwidth signal processing. The demonstrated optoelectronic architectures benefit from the use of holographic components and of the advanced concepts of optical holography transposed in the microwave spectral regions. (Iezekiel, 2009; Zhu et al., 2021; Vandelle et al., 2022).

Computer-generated holograms and diffractive optics

The purpose here is the same as for optically recorded holography. It is to reconstruct a desired wave front, but the process is different since no physical recording process is involved. The wave front is entirely computed and this brings flexibility and versatility.

Initially, the word computer-generated hologram (CGH) was used, but presently, it is often referred to as a diffractive optical element (DOE). A. Lohmann proposed the first CGH in 1967, and since then computation algorithms and fabrication methods have evolved following the progress of computers as well as the development of new fabrication technologies based on micro-lithography techniques. Presently, the DOEs can be classified into two classes (Kress and Meyrueis, 2009): analytical-type DOEs and numerical-type DOEs.

Analytical-type DOEs

The data composing such a DOE are in an analytical form and this is the case for diffractive lenses or gratings. These DOEs are pure phase elements and are fabricated accordingly. There are different approaches for the design of analytical-type DOEs, the direct DOE computation, the interferogram approach, and also the use of optical-design software.

Numerical-type DOEs

For this type of DOEs, the wave front to be reconstructed cannot be described by an analytical equation but must be computed using the propagation law. If the CGH illuminated by a plane wave reconstructs the desired wave front in the focal plane of a converging lens, the CGH will contain the inverse FT of the desired construction. If the CGH reconstructs without a lens at a given distance, then it will contain the inverse Fresnel transform of the desired reconstruction. The result of the Fourier or Fresnel transform is a 2D array of complex values. As for optically recorded holograms, the recording media are pure amplitude (mostly binary) or pure phase media, and therefore the complex data must be encoded to satisfy the requirements of the fabrication techniques. There are two types of encoding: first one is the cell-oriented encoding, and the second is the point-oriented encoding.

The first CGH presented by A. Lohmann used a cell-oriented encoding that he called phase-detour encoding (Lohmann and Paris, 1967). The hologram is a 2D array of cells representing the array of complex values, and an aperture in each cell represents each complex value. The surface of this aperture is proportional to the amplitude of the complex value to be encoded and its position in relation to the center of the cell is proportional to the phase. An adequate ratio between the aperture width and the cell size introduces the right carrier frequency that allows the separation of the central order from the two reconstructed orders (see Fig. 7). This encoding, known now as Lohmann's encoding, has given rise to several variations such as the encoding presented by W. H. Lee with two apertures per cell (Lee, 1970). The computation of these CGHs does not require powerful computers and is not time-consuming since only one Fourier or Fresnel transform is calculated. Originally, these CGHs were first drawn on a sheet of paper with a computer-controlled pen plotter and then photoreduced on a high-resolution photographic film.

In the 1980s, thanks to the progress of computers in terms of power and memory capacity, several point-oriented encoding methods were developed. The principle of the three main methods is described below. For these algorithms, the desired reconstruction window is placed into a larger 2D array, therefore the hologram and also the reconstruction plane is larger than the

Fig. 7 Lohmann hologram: (A) the negative of the hologram and (B) optical reconstruction. From Ambs P, Huignard JP, and Loiseaux B (2016) *Holography, Reference Module in Materials Science and Materials Engineering*. Elsevier.

reconstruction window. This extra space allows a better convergence of the computation algorithm due to the phase and amplitude freedom outside the reconstruction window. Amplitude CGHs construct the desired reconstruction, its complex conjugate, and a zero order. In order to separate these terms, the reconstruction window should be placed at some distance from the center of the reconstruction plane. For phase CGHs with more than three-phase levels, only the desired reconstruction window appears in the reconstruction plane with no zero and no complex conjugate orders. However, this happens only if the computed phase levels are perfectly reproduced by the CGH.

The error diffusion algorithm consists of using a pulse width modulation technique for binarizing the hologram (Hauck and Bryngdahl, 1984). In the case of binary amplitude CGHs, the real part of the Fourier or Fresnel transform is made positive by adding an offset, and then normalized. Each of these sampled real values is binarized and the error, that is, the difference between the binary value and the analog value, is divided and distributed with a weight to the unprocessed neighbors before proceeding to the next point. By choosing the weight and the direction of the error diffusion carefully, it is possible to separate the quantization noise from the desired reconstruction. This algorithm has given rise to a lot of related algorithms, such as the complex error diffusion algorithm (see Fig. 8).

The next two encoding methods that are presented are iterative methods, they give better results in terms of signal-to-noise ratio (SNR) but their computation is more time-consuming.

The direct binary search (DBS) algorithm presented by Seldowitz and co-workers in 1987 (Seldowitz et al., 1987) is based on the optimization of an error criterion by the use of a Monte Carlo technique. To begin with, a random hologram is generated, and the error criterion between the desired image and the reconstruction of this hologram is computed. The random CGH is then scanned, and a new error is computed after inversion of a new pixel. Pixel modification is retained only if the error decreases, and the error criterion is thereby minimized. This cycle is stopped when the error stops decreasing. The error criterion can be defined for amplitude, intensity, or a complex image, depending on the application using the CGH. For some applications, the CGH must reconstruct a wave front with a specified amplitude and phase, and the error must then be based on a complex-amplitude error criterion. However, in many other applications (display, memory, interconnect, etc.) the CGH reconstruction is detected by a quadratic detector, leaving the phase as a free parameter, and the error criterion can be based on amplitude or intensity errors. Since

these errors use the phase freedom, the optimization algorithms converge better in this case. The original DBS algorithm was designed for binary CGHs; however, it can be extended to multilevel amplitude or phase CGHs at the expense of the computation time, since for each pixel, all levels must be tested.

The iterative Fourier transform algorithm (IFTA) presented in 1988 by F. Wyrowski (Wyrowski and Bryngdahl, 1988), is an iterative technique based on the Gerchberg–Saxton algorithm (Gerchberg and Saxton, 1972). Schematically, the principle of this method consists in going successively from the object plane to the spectrum plane by the application of constraints on the CGH (see Fig. 9). To be recorded, the CGHs must be quantized and often binarized, but IFTA can also be used to compute multilevel amplitude or phase CGHs. In the Fourier domain, the spectrum of the object is thus constrained to be a binary function. The object constraint must correct the quantization noise by injection of the desired image intensity in the signal windows. The inverse FT of this spectrum gives back an object plane in which the object constraint is thus applied to match the desired image intensity in the signal windows. However, to avoid stagnation of the algorithm the quantization of the spectral plane must be progressive, as is illustrated in Fig. 9, where three different steps of the binarization process are shown. In order to make its spectrum as uniform as possible, an equalizer can be applied to the desired signal. The simplest equalizer adds a random diffuser to the object plane.

For multilevel amplitude or phase CGHs, a multilevel progressive quantification is applied to the amplitude or the phase of the spectrum. Excellent quality phase CGHs can be fabricated using an IFTA method, they exhibit a high diffraction and a reconstruction with a high signal-to-noise ratio (see Fig. 10).

Today, most of the CGHs are computed using IFTA based methods. Compared to the other algorithms for computing CGHs, the CGHs computed with IFTA have the best tradeoff between the computing time and the quality of the reconstruction. Moreover, IFTA can be adjusted to fit the desired application. CGHs design software products are now commercially available.

Quality DOEs imply a very precise manufacturing with a perfect match between the computed phase and the actual phase of the component. To achieve these requirements, microlithography techniques are used to etch very precisely, in shape and depth, the chosen optical substrate such as quartz. Embossing techniques make cheaper DOEs, but the quality of their reconstruction is lower, particularly as the phase mismatch generates a zero order. Dynamic DOEs can also be implemented by displaying the DOE on a spatial light modulator (SLM). Liquid crystal on silicon (LCoS) SLMs with zero-twist nematic liquid crystal are particularly well suited for dynamic DOEs since they are pure phase modulators of the illuminating light and therefore allow a high diffraction

Fig. 10 The optical reconstruction of an IFTA encoded 8-level phase dynamic CGH displayed on a pure phase SLM. The reconstructed image is 128×26 pixels, and a 512×512 pixel hologram was computed and replicated to be displayed on the 792×600 pixels SLM. Due to a perfect phase matching, no complex conjugated order is appearing in the reconstruction.

Fig. 11 Generation of a non-diffracting beam with a computed analytical DOE. Experimental results: (A) Phase DOE displayed on a pure phase LCoS SLM. (B–E) beam intensity measured at different distances from the SLM. (B) at 0.70 m, (C) at 0.90 m, (D) at 1 m, (E) at 1.2 m.

efficiency reconstruction of the DOE without the complex conjugated term. Following this approach CGH displayed on a very high-resolution LC-SLM were demonstrated for automotive head-up display of 3D images. (Skirnewskaja et al., 2021).

DOEs have a broad range of applications sectors such as industrial, defense, optical telecommunications, biotechnology, entertainment, and consumer electronics (Turunen and Wyrowski, 1997). The number of applications is expanding and includes for example laser beam shaping, Fourier filtering for optical image processing, 2D display (Fig. 10) and 3D display, structured light illumination for 3-D sensing, optical interconnects, hybrid lens, illumination of photovoltaic solar cells, diffractive encoders, optical tweezers, endoscopic imaging, complex optical functions generation.

DOEs can be used for beam shaping and generation of complex wavefront (Davis et al., 1996; Dudley et al., 2013; Li and Wang, 2017; Mestre et al., 2007). For example, an analytical DOE was computed for the creation of a higher order nondiffracting Bessel beam. Fig. 11A shows this DOE displayed on a pure phase LCoS SLM. Figs. 11B–E show the experimental results when the SLM is illuminated by a plane wave. The intensity of the beam at different distances from the SLM demonstrates that the wavefront remains constant over this range.

Digital holography

In digital holography (DH), the recording media is replaced by a high-resolution electronic camera. Using data from the recorded interference pattern, the object is reconstructed by a digital computer. Digital holography is a fast-growing field, because it suppresses all the difficulties related to the processing of the traditional holographic recording media and brings in a lot of versatility and flexibility and thus stimulated a lot of research and development works relevant to the theory and applications of the digitally restored images from interferograms detected on a CCD detector matrix (Schnars et al., 2015).

Digital holography is now used in industrial applications requiring a quantitative measurement of a wave front where it is successfully replacing the classical setups (Schnars et al., 2015). Fig. 12 shows the measurement of deformations using digital holography.

Therefore, digital holography is becoming a technique now widely used in applications to metrology, microscopy, polarization, Doppler and phase imaging. . . (Javidi et al., 2021). Also encrypted DH permits to realize novel applications for information security, in particular when using optical or digital correlation methods for object recognition (Javidi, 2005). DH allows obtaining the amplitude and phase of incident optical fields by phase shifting digital holography: a technique that consists of recording several holograms of the incident field with different known values of the phase on the reference wave. For each application both on axis and off axis configurations are implemented according to the spatial resolution of the pixels of the detection matrix and also in

theory, the noise of the detected interferogram is limited by the shot noise of the reference wave (Gross and Atlan, 2007; Verpillat et al., 2010). Another important advantage in favor of using digital holography is the development of high-performance several megapixels CCD – CMOS technologies in terms of the number of pixels, very small pixel size, low noise, and readout speed. When also considering the most recent advances in digital processing of the detected interferograms on video signals, it appears clearly that digital holography will continue to expand applications in a large diversity of fields and thus demonstrates very interesting performances.

A rapidly expanding field of application concerns the digital holographic microscopy (DHM) that allows a subnanometer vertical resolution (CuChe et al., 1999; Emery et al., 2021). Digital holographic microscopes are now commercially available.

Another important application is in the field of biophotonics where DH can perform both the imaging of the eye retina and the Doppler image of blood cells flowing in the vessels. Note that to operate in real time, this application requires the development of algorithms to stabilize the image and to compensate for the aberrations introduced by the eye. In this experiment, the temporal resolution permits observing the changes of blood flow with the cardiac cycles and confirm interest for medical diagnostics of eye diseases. The Fig. 13 illustrates such full-field images of the retina vessels under very low laser illumination and are obtained by laser Doppler holography at a wavelength of 852 nm (Puyo et al., 2018).

DH still continues to evolve and to demonstrate original experiments issued of the advanced techniques of very high precision optical metrology and spectroscopy and based on interferometers with two laser frequency combs. As an example, this is demonstrated in the recently published work (Vicentini et al., 2021) which develop a novel and powerful method of dual comb hyperspectral digital holography providing both 3D spatial and spectral imaging.

Artificial surfaces

1. Birefringing optical materials based on holographic techniques

Artificial optical materials exhibiting birefringence can be obtained by volume holographic recording technics in high resolution photosensitive materials. Artificial birefringence is achieved with a thick sinusoidally index grating if the grating period of the index modulation is small compared to the operating wavelength range (about a factor of 10). Under such conditions, all non-zero diffraction orders are evanescent and the grating is equivalent to a negative uniaxial birefringent material of optical axis normal to the index layers.

The ordinary and extraordinary index can be calculated (Campbell and Kostuk, 1995) for a volume holographic grating with a sinusoidal index modulation so that the holographic film behaves as a negative uniaxial medium. This has been experimentally demonstrated by Kim et al. (1995) with dichromated gelatin as holographic material and by Yang and Yeh (1996, 1997) in DuPont photopolymer films. As an example of applications, it was applied in reference (Joubert et al., 2002) to TN-LCD for widening their viewing angle.

2. Optical metasurface

The recent progress in nano-fabrication opened the route to new solutions for optical holography based on sub-wavelength elements, more generally called metasurfaces. Such optical metasurfaces have been recently identified as a future game changer to simplify bulky optical systems. They are generally described by light propagation methods based on either coherent scattering from each optical nano-antenna composing the optical surface or holographic synthesis. A wide range of applications based on new optical components offering efficient wavefront construction, polarization control are already proposed (Lalanne and Chavel, 2017; Spägle et al., 2021; Chen and Capasso, 2021; Huang et al., 2016; Wu et al., 2018).

3. Metasurface holography

The first demonstration of metasurface holography, was proposed in the infrared (Larouche et al., 2012) consisting of multilayers of metamaterials based on I-shape nanostructures, as reported by Linling Huang in its review of Nanophotonics (Huang et al., 2018; Lee et al., 2017; Malek et al., 2017).

4. Active metasurface

Active metasurfaces have been foreseen by N.L. Zheludev (Zheludev and Kivshar, 2012), during the first decade of the 21st century as opening new application fields with the introduction of new active elements in various nanophotonic systems. More recently, active metasurfaces integrating various functional materials or effects have been reported, among others: active devices based on phase change materials (Minovich et al., 2015; Chaudhary et al., 2019) (germanium antimony tellurium alloy $\text{Ge}_2\text{Sb}_2\text{Te}_5$, vanadium dioxide VO_2), 2D materials (Xu et al., 2013) (graphene, borophene), thermal effect phased arrays (Sun et al., 2013), electro-optical modulations (Smalley et al., 2013), liquid crystals (Kobashi et al., 2016) and programmable gate arrays (Li et al., 2017).

Fig. 14 as an example of application from Li et al. (Li et al., 2015) illustrates the extension of multilevel phase holography with a pixel-level independent control of active elements based on reduced graphene-oxide (rGO) materials. Such materials pave the way to new design of active phased array optical antennas for which efficiency, field of view, signal-to-noise ratio have to be improved.

Fig. 14 Reprogrammable multi-level phase holography based on reduced graphene-oxide (rGO) controlled by fs laser pulse. (A) Schematic illustration of the optical digitalization of refractive-index/phase modulation by the athermal photoreduction using a single fs pulse. The subwavelength-scale phase modulation from 0 to π is finely tuned by the intensity of a fs beam. The area-by-area parallel digitalization is achieved through an objective capable of generating MMAs with variant intensities in each focal spot corresponding to the phase correlation. (B) Scheme of wide-angle 3D images by confining the photoreduction at a subwavelength scale through increasing the NA of the parallel digitalization objective. Conclusion

Even if holography was invented in 1948 by Denis Gabor, it is only in the beginning of the 1960s that it expanded rapidly with the availability of a coherent light source, the laser. Until today, holography continues its development benefiting from the scientific and technical progress of the last 60 years.

Optical holography has a broad range of applications initially driven by 3D display and security holograms up to the more recent fields of AR, VR and XR. A new branch of optical holography has emerged thanks to the impressive progress of CMOS cameras and of the power of computers, it is digital holography, where the hologram is recorded by a camera and reconstructed by a digital computer. Digital holography brings in a lot of versatility and flexibility enabling numerous applications such as in industrial metrology, digital holographic microscopy, biophotonics imaging, and laser manufacturing.

Computer generated holography, taking advantage of the progress in the fabrication technologies coming from the semiconductor industry, has given rise to the field of DOEs. DOEs have a broad and expanding range of applications going from industry to consumer electronics through sectors such as defense, security, optical telecommunications, biotechnology.

Also, the holography has extended its concepts in the fields of nonlinear optics and in microwave optics. Here the coherent wave mixing of signal and pump beams in a nonlinear media induces a dynamic hologram enabling to amplify and to control amplitude and phase of complex signal waves carrying spatial and temporal information.

Nanotechnology and recent research in artificial surfaces and metamaterials show that holography always continue to stimulate novel ideas and progress of the technology thus leading to a bright future for innovative fields of applications.

Abstract

Causality implies the Kramers-Kronig (KK) relations linking the real and imaginary parts of any response function. They have a fundamental importance in optics allowing, for instance, a determination of the absorption at any frequency from the measurement of the reflectivity on the entire spectrum. Most importantly, the KK dispersion relations also lead to a large number of sum rules, among which the Thomas-Reiche-Kuhn (TRK) sum rule for the absorption coefficient and the Altarelli-Dexter-Nussenzweig-Smith (ADNS) sum rule for the refractive index. These important results have long been known in linear optics, but they have also been generalized to non-linear optics.

Key points

- linear response
- non-linear response
- causality
- Kramers-Kronig dispersion relations
- sum rules
- dielectric function
- non-linear susceptibilities

Introduction

The optical properties of atoms, molecules, and solid materials have been an active field of research for the past two centuries and have given the most precise information on the microscopic structure of matter (Greenway and Harbeke, 1968; Bassani and Pastori-Parravicini, 1975; Bassani and Altarelli, 1983). Since the early 19th century it was known that absorption peaks occur at specific frequencies and that a corresponding dispersion shows up in the frequency dependence of the dielectric function $\varepsilon(\omega)$ (or in the refractive index $n(\omega)$).

We recall that in any medium all the optical functions (dispersion, absorption, reflection, ...) depend on the frequency ω and on the momentum of the photon $\hbar\vec{k} = \hbar\frac{2\pi}{\lambda}$, $\hbar$ being the reduced Planck constant. They can all be expressed in terms of the complex dielectric function $\tilde{\varepsilon}(\vec{k}, \omega)$. In crystalline materials the optical constants are tensors (second-rank tensors in the linear

*Deceased.

approximation), but this aspect may be neglected for our purposes. For electromagnetic waves the magnetic susceptibility is considered unitary and one can also use the dipolar approximation ($\vec{\hbar k} \simeq 0$) because of the very small light momentum (neglect of spatial dependence).

From Maxwell equations it can be seen that the imaginary part of the dielectric function can be expressed in terms of the conductivity σ , so that

$$\tilde{\epsilon}(\omega) = \epsilon_1(\omega) + i\epsilon_2(\omega) = 1 + 4\pi\chi(\omega) + \frac{4\pi\sigma(\omega)}{\omega}i, \quad (1)$$

where the subscripts 1 and 2 denote real and imaginary part, respectively, and the real susceptibility χ is defined in terms of the polarization $\vec{P}$ (dipole moment per unit volume) and of the electric field $\vec{E}$ by

$$\vec{P}(\omega) = \chi(\omega)\vec{E}(\omega). \quad (2)$$

If the susceptibility is also extended to include the conductivity, so that

$$\tilde{\chi}(\omega) = \chi(\omega) + \frac{i\sigma(\omega)}{\omega} = \chi_1 + i\chi_2, \quad (3)$$

the usual expression for the complex dielectric function follows $\tilde{\epsilon}(\omega) = 1 + 4\pi\tilde{\chi}(\omega)$. The complex refractive index is defined as

$$\tilde{n}(\omega) = \sqrt{\tilde{\epsilon}(\omega)} = n(\omega) + i\kappa(\omega). \quad (4)$$

The absorption of radiation can be related to the conductivity induced by the electric field by considering the energy lost per unit time per unit volume

$$\frac{dW}{dt} = \vec{J} \cdot \vec{E} = \frac{d\vec{P}}{dt} \cdot \vec{E} = \sigma E^2, \quad (5)$$

so that the absorption coefficient $\eta(\omega)$, defined as $\frac{dW}{dx} = -\eta W = \frac{dW}{dt} \frac{n}{c}$, is given by

$$\eta = \left| \frac{dW}{dt} \right| \frac{n}{Wc} = \frac{4\pi\sigma}{nc} = \frac{\omega\epsilon_2}{nc} = \frac{2\omega\kappa}{c}. \quad (6)$$

Also the reflection and transmission amplitudes can be obtained from the dielectric function through Fresnel relations, which in the case of normal incidence from vacuum to a medium are

$$\frac{E_r}{E_0} = r = \frac{\tilde{n} - 1}{\tilde{n} + 1}, \quad \frac{E_t}{E_0} = t = \frac{2}{\tilde{n} + 1}, \quad (7)$$

$R = |r|^2$ and $T = |t|^2$ being the reflectivity and the transmittance, respectively.

The above described optical functions give the electromagnetic properties of matter. Their detailed dependence on frequency is related to the microscopic structure of the material considered and to its interaction with the radiation field (Greenway and Harbeke, 1968; Bassani and Pastori-Parravicini, 1975; Bassani and Altarelli, 1983). We will here consider general properties of the linear (Bassani, 2005a) and nonlinear (Bassani, 2005b) optical functions which only depend on time causality.

Elementary description of sum rules

The traditional phenomenological model for the optical constants is the Lorentz oscillator model, where the equation of motion of a specific electron with oscillator frequency ω_j and damping γ_j is given by

$$\frac{d^2x}{dt^2} + \omega_j^2 x + \gamma_j \frac{dx}{dt} = \frac{eE}{m}. \quad (8)$$

From this one obtains for the complex dielectric function in a volume V for a number of resonance frequencies ω_j

$$\tilde{\epsilon}(\omega) = 1 + \frac{4\pi e^2}{mV} \cdot \left(\sum_j \frac{f_j}{(\omega_j^2 - \omega^2) - i\gamma_j\omega} \right), \quad (9)$$

where the oscillator strength f_j gives the intensity of the resonance at frequency ω_j with damping constant γ_j . The conservation of the electron number and the asymptotic behavior ($\omega \rightarrow \infty$) of (9), made to coincide with that of free electrons ($f_j = 1, \omega_j = 0, \gamma_j = 0$) gives immediately the f -sum rule, first demonstrated in 1925 by W. Thomas, F. Reiche and W. Kuhn, and called the TRK sum rule:

$$\sum_j f_j = N. \quad (10)$$

This states that the sum of the oscillator strengths of all optical transitions is equal to the total number of electrons N .

Although the TRK sum rule was derived with classical mechanics it is worth mentioning that the quantum description of the oscillator strength implies that, for the sum rule to hold, also the commutation relation between momentum and position operator must hold, as pointed out by Heisenberg. In fact one can see, by expressing the optical functions in terms of the transition probability rates, observing that electrons are excited from state i to state f , with a probability rate given by the Fermi golden rule

$$P_{if} = \frac{2\pi}{\hbar} |f|eEx|i|^2 \delta(E_f - E_i - \hbar\omega), \quad (11)$$

that the quantum mechanical expression for the imaginary part of the dielectric function is

$$\varepsilon_2(\omega) = \frac{4\pi^2}{V} \sum_{ij} |f|eX|i|^2 \delta(E_f - E_i - \hbar\omega). \quad (12)$$

Considering in expression (9) that

$$\lim_{\gamma \rightarrow 0} \frac{\gamma}{(\omega_j - \omega)^2 + \left(\frac{\gamma}{2}\right)^2} = 2\pi \delta(\omega_j - \omega), \quad (13)$$

one obtains the quantum-mechanical expression of the oscillator strength

$$f_{fi} = \frac{2m}{\hbar^2} |\langle f|x|i \rangle|^2 (E_f - E_i). \quad (14)$$

Taking into account the general Heisenberg expression for the time dependence of the displacement x

$$m\dot{x} = \frac{m}{i\hbar} [x, H], \quad (15)$$

where the square brackets denote commutators, and considering the eigenstates expression

$$H|j\rangle = E_j|j\rangle, \quad (16)$$

one obtains for the oscillator strength

$$f_{fi} = \frac{2m}{\hbar^2} \langle i|x|f \rangle \langle f|x|i \rangle (E_f - E_i) = \frac{1}{i\hbar} (\langle i|x|f \rangle \langle f|p_x|i \rangle - \langle i|p_x|f \rangle \langle f|x|i \rangle), \quad (17)$$

which, summing over the final states, gives

$$\sum_f f_{fi} = \frac{1}{i\hbar} \langle i|[x, p_x]|i \rangle = 1, \quad (18)$$

because of Heisenberg commutation rules $[x, p_x] = i\hbar$. Summing over all occupied initial states, one obtains immediately the TRK sum rule (10).

In general the oscillator strength, depends continuously on the frequency, so that the TRK sum rule can be expressed in terms of the imaginary part of the dielectric function as

$$\int_0^\infty \omega \varepsilon_2(\omega) d\omega = \frac{2\pi^2 e^2}{m} Q, \quad (19)$$

which relates the total radiation absorbed to the total electron density $Q = N/V$.

This is a very important property, because it gives a general constraint which the absorption of the medium must obey. When the sum rule (19) is saturated at a given frequency no further absorption can occur at higher frequencies. This explains why in light elements (low electron density) hard X-rays are not absorbed and hard γ -rays pass through all materials. The sum rule (19) is also useful to check the results of approximate calculations or experiments. It must always be obeyed by the exact optical functions.

Kramers-Kronig dispersion relations

A connection between sum rules and the causality principle was established on the basis of the relation between the real and the imaginary part of the susceptibility $\tilde{\chi}(\omega)$. This can be obtained by considering the complex ω plane and observing that the susceptibility does not have poles on the upper plane because the polarization can be expressed from the time dependent response operator $G(\tau)$ as

$$P(t) = \int_{-\infty}^{+\infty} G(\tau) E(t - \tau) d\tau, \quad (20)$$

with the condition $G(\tau) = 0$ for $\tau < 0$ due to time causality. Then, taking the Fourier transform, one obtains

$$P(\omega) = \tilde{\chi}(\omega) E(\omega), \quad (21)$$

with

$$\tilde{\chi}(\omega) = \int_0^\infty G(\tau) \exp[i\omega\tau] d\tau. \quad (22)$$

The fact that $\tilde{\chi}(\omega)$ is analytic in the upper complex plane gives, using Cauchy theorem on a contour closed to infinity where $\tilde{\chi}(\omega)$ goes to zero (see Fig. 1)

$$\tilde{\chi}(\omega) = \frac{1}{\pi i} \int_{-\infty}^{+\infty} \frac{\tilde{\chi}(\omega')}{\omega' - \omega} d\omega', \quad (23)$$

Fig. 1 Indication of the contour on the complex plane where the integral of the function $\chi(\omega')/(\omega' - \omega_0)$ by Cauchy theorem is equal to $i\pi\chi(\omega_0)$. From Bassani F (2005a) Optical Sum Rules and Kramers-Kronig Relations. ECMP 1st edn.

where the line on the integral denotes that the principal part must be considered. Since $\chi(-\omega) = \chi^*(\omega)$, one obtains the standard form of Kramers-Kronig (KK) relations

$$\chi_1(\omega) = \frac{2}{\pi} \int_0^\infty \frac{\omega' \chi_2(\omega')}{\omega'^2 - \omega^2} d\omega', \quad (24)$$

$$\chi_2(\omega) = -\frac{2\omega}{\pi} \int_0^\infty \frac{\chi_1(\omega')}{\omega'^2 - \omega^2} d\omega'. \quad (25)$$

In the case of metals, besides the pole at ω , the function $\frac{\tilde{\chi}(\omega')}{\omega' - \omega}$ has an additional pole at $\omega' = 0$ because $\sigma(0) \neq 0$. This can be taken into account by considering the function $\tilde{\chi} - \frac{\sigma(0)}{\omega} i$, which does not have such a pole and is analytic on the upper plane. Then dispersion relations (23) and (24, 25) apply, provided the term $\frac{\sigma(0)}{\omega}$ is added to the imaginary part of $\tilde{\chi}(\omega)$ and the principal part of the integrals is considered along all the real axis, including the point at $\omega = 0$, where $\tilde{\chi}_2(\omega')$ has a pole.

The above KK relations are very useful because they relate the dispersion to the absorption. Similar relations can be obtained for the other optical constants $\tilde{\sigma}, \tilde{n}(\omega), r$, and $\text{Im}(\frac{1}{\epsilon})$.

They can be all connected to specific sum rules by considering the asymptotic behavior which can be obtained from the KK relations, and comparing it to that which follows from a specific model of the material system. Since the asymptotic behaviors must coincide, sum rules are obtained. We can see immediately that the TRK sum rule (10) or (19) can be obtained when we consider the asymptotic behavior from (24) by using the so called superconvergence theorem, which amounts to letting $\omega' \rightarrow 0$ in the denominator, and comparing it with the asymptotic behavior from expression (9) ($\omega_j \rightarrow 0$ in the denominator).

As a consequence of the above discussion, we can conclude that sum rules and KK dispersion relations derive from the causality principle only, and from the knowledge of the short-time (or high frequency) behavior of the system. Complicated properties due to electron-electron interaction or external potentials are not relevant for sum rules and Kramers-Kronig relations. Also not essential is the quantum-mechanical approach.

A revival of the field of sum rules started in the early 1970s after the discovery of the refractive index sum rule by Altarelli, Dexter, Nussezevig and Smith (ADNS) which states for the real part of the refracting index

$$\int_0^\infty (n(\omega) - 1) d\omega = 0. \quad (26)$$

After that new sum rules and more KK-type relations were derived for all optical functions and are now being used to interpret a variety of effects. New K-K relations and sum rules have also been found in nonlinear optics. Sum rules can be now explored in the entire frequency range using the properties of synchrotron radiation. They are also being used as stringent tests for approximate theories.

Kramers-Kronig relations and linear sum rules

We have derived KK relations (24), (25) for the complex susceptibility function by direct integration, but causality and KK relations have more direct implications; they can be summarized in what is known as a Titchmarsh theorem which states the following (Titchmarsh, 1968). Any square integrable function $f(\omega)$ which fulfills one of the three conditions below fulfills all three of them:

- (i) the inverse Fourier transform $F(t)$ of $f(\omega)$ vanishes for $t < 0$,

- (ii) $f(\omega)$ is the limit for $\varepsilon \rightarrow 0^+$ of a functions $\tilde{f}(\omega + i\varepsilon)$ that is analytic in the upper half plane and square integrable on the real axis and on any line parallel to it,
 (iii) $\tilde{f}(\omega)$ verifies the KK identity

$$\tilde{f}(\omega) = \frac{1}{\pi i} \int_{-\infty}^{\infty} \frac{\tilde{f}(\omega')}{\omega' - \omega} d\omega', \quad (27)$$

or equivalently for $F(t)$ real,

$$\begin{aligned} f_1(\omega) &= \frac{2}{\pi} \int_0^{\infty} \frac{\omega' f_2(\omega')}{\omega'^2 - \omega^2} d\omega', \\ f_2(\omega) &= -\frac{2\omega}{\pi} \int_0^{\infty} \frac{f_1(\omega')}{\omega'^2 - \omega^2} d\omega'. \end{aligned} \quad (28)$$

The above theorem proves that KK relations are a direct consequence of causality, but it also implies that any combinations of analytic functions satisfies KK relations if they are square integrable. For establishing KK relations one does not need to know the explicit form of the causal response function, which is determined by the specific operator being considered, by the Hamiltonian, and by the time-dependent perturbing potential. One only needs to know its asymptotic behavior which can be obtained in the classical approximation from the Lorentz oscillator model, or in the quantum theory from the quantum expression of the response function at zero-time. The same holds for the sum rules, which are obtained by comparing the above described asymptotic behavior with that obtained from KK relations.

Let us consider the optical case in the dipole approximation. The interaction Hamiltonian can then be written as

$$H' = -\vec{P} \cdot \vec{E}(t), \quad (29)$$

where $\vec{P} = \sum_i e \vec{r}_i$ is the polarization (it can be used as an operator in quantum mechanics) and $\vec{E}(t)$ is the electric field, which is taken as a sinusoidal function. While in the classical approximation one considers directly the time dependence of the polarization (Lorentz oscillator model), in the quantum mechanical approach the response function can be obtained from the trace of the density matrix operator ρ_0 on the ground state of the system, and to first order is given by

$$G(\tau) = \text{Tr} \left\{ \frac{1}{i\hbar} [P(-\tau), \rho_0] P \right\}, \quad (30)$$

where $P(\tau)$ is defined in the interaction representation. This gives for the susceptibility the expression

$$\chi(\omega) = \frac{1}{\hbar} \sum_n |0|P|n|^2 \left\{ \frac{1}{\omega + \omega_{n0} + i\varepsilon} - \frac{1}{\omega - \omega_{n0} + i\varepsilon} \right\}, \quad (31)$$

where ε is an arbitrarily small frequency which accounts for the adiabatic switching on of the perturbation.

The sum rules can now be obtained from the two expressions of the asymptotic behavior, which must coincide. The first is given by the zero-time response function and its derivatives, and can be obtained integrating by part the Fourier transform of $G(\tau)$, with $G(\infty) = 0$. One obtains

$$\begin{aligned} \chi_{\omega \rightarrow \infty}(\omega) &= \int_0^{\infty} G(\tau) \exp[-i\omega\tau] d\tau = \\ &= \frac{G(0^+)}{-i\omega} + \frac{G'(0^+)}{-\omega^2} + \frac{G''(0^+)}{-i\omega^3} + \frac{G'''(0^+)}{\omega^4} + \dots, \end{aligned} \quad (32)$$

where the time derivatives are denoted with the apex. The second is obtained from the KK relations (24) with the superconvergence theorem,

$$\chi_1 = -\frac{2}{\pi\omega^2} \int \omega' \chi_2(\omega') d\omega' + O(\omega^{-2}), \quad (33)$$

$$\chi_2 = \frac{2}{\pi\omega} \int \chi_1(\omega') d\omega' + O(\omega^{-1}). \quad (34)$$

By computing the limits of expression (32) it can be seen that $G(0^+) = 0$, $G'(0^+) = \omega_p^2/4\pi$, etc. Then, two sum rules are immediately obtained: The first from the asymptotic behavior of the real part is the TRK sum rule

$$\int_0^\infty \omega' \chi_2(\omega') d\omega' = \frac{\pi}{2} \frac{d}{dt} G(t) \Big|_{t=0^+} = \frac{1}{8} \omega_p^2, \quad (35)$$

where $\omega_p^2 = \frac{4\pi e^2 Q}{m}$. The second refers to the asymptotic behavior of the imaginary part of the susceptibility which, by comparing with (32) is

$$\int_0^\infty \chi_1(\omega') d\omega' = \frac{\pi}{2} G(t) \Big|_{t=0^+} = 0, \quad (36)$$

where the second equality can be obtained from the quantum-mechanical expression of $G(t)$ or from the Lorentz oscillator model.

In the case of metals the imaginary part of $\chi(\omega)$ has a pole $\omega = 0$ due to the fact that the conductivity $\sigma(\omega)$ is different from zero at zero frequency. As shown for the KK relations, this can be handled by adding to $\tilde{\chi}(\omega)$ the term $\left(-\frac{\sigma(0)}{\omega} i\right)$ which cancels the pole, preserving the properties of the function. This is the dominant term in the asymptotic behavior for $\omega \rightarrow \infty$, so that, by comparing with (34) one obtains the sum rule for metals:

$$\int_0^\infty \chi_1(\omega') d\omega' = \frac{\pi}{2} \sigma(0). \quad (37)$$

Other similar sum rules can be obtained for all optical constants (conductivity σ , refractive index $\tilde{n}, \varepsilon^{-1}(\omega)$) in the same way, above described, because they are all related to the real and imaginary part of the susceptibility. Analogously to eq. (36) is the ADNS sum rule for the real part of the index of refraction which can be obtained immediately from the observation that the dispersion relations (28) apply to $\tilde{n}(\omega) - 1$ for both the metallic and nonmetallic media and that the asymptotic behavior of the complex refractive index is

$$\tilde{n}(\omega) \underset{\omega \rightarrow \infty}{\simeq} 1 - \frac{\omega_p^2}{2\omega^2} + O(\omega^{-2}). \quad (38)$$

As a consequence one obtains the ADNS sum rule (26) for both metallic and nonmetallic media.

Applications of the above described sum rules and KK relations are innumerable and have been of great help in understanding the basic properties of optics in condensed matter. They explain immediately why above a given frequency all materials are transparent to the electromagnetic radiation.

They show immediately the strict connection between the absorption edge in solids and the value of the static dielectric constant.

The KK dispersion relations have allowed the determination of the optical constants from the measurements of only one of them on the entire optical spectrum (for instance the reflectivity in semiconductors, where the transmittance cannot be measured because it is too small). In that case dispersion relations can be derived for the reflectivity amplitude $r = |r| e^{i\theta}$. They connect the measured reflectivity R to the phase θ through the function

$$\ln r = \ln |r| + i\theta = \frac{1}{2} \ln R(\omega) + i\theta(\omega), \quad (39)$$

which has been proven to have the required analytic behavior in the upper half of the complex ω plane. One can then obtain the phase, and from eq. (7) the complex refractive index and all optical constants. This has extended the knowledge of the optical transitions in solids, and consequently of the electronic band structure over an extended energy range.

The availability of synchrotron radiation over a very extended frequency range has furthermore allowed the direct verification of the sum rules. The results obtained on the metal Al are reported in Fig. 2 (Shiles et al., 1980).

Relativistic and spatial dependent corrections

One can extend the sum rules beyond the dipole approximation, by considering spatial dispersion and the relativistic definition of the current from Dirac equation. One must consider the fact that $\vec{k}$ is related to ω by the expression $\varepsilon(k, \omega)\omega^2 = k^2(\omega)c^2$ so that one must take this into account when performing the integration over frequency.

One can be limited to first-order contributions in k^2 because of the small value of $|\vec{k}|$ in optics. The lowest-order contribution is of order k^2 because the linear term vanishes due to time reversal. Following Ginzburg and Meiman a Taylor expansion about $k = 0$ can be obtained as

$$\varepsilon\left(\frac{\omega\sqrt{\varepsilon}}{c}, \omega\right) \simeq \varepsilon(0, \omega) + \frac{\omega^2}{2c^2} \varepsilon\left(\frac{\omega\sqrt{\varepsilon}}{c}, \omega\right) \frac{\partial^2 \varepsilon}{\partial k^2} \Big|_{k=0}, \quad (40)$$

which gives

$$\varepsilon\left(\frac{\omega\sqrt{\varepsilon}}{c}, \omega\right) \simeq \frac{\varepsilon(0, \omega)}{1 - \frac{\omega^2}{2c^2} \frac{\partial^2 \varepsilon}{\partial k^2} \Big|_{k=0}}. \quad (41)$$

Fig. 2 Sum rule for ϵ_2 , κ and $-\text{Im}(\epsilon^{-1})$: in Al the solid line shows the saturation at $n = 13$. Reproduced with permission from Shiles E, Sasaki T, Inokuti M, and Smith DY (1980) Self-consistency and sum-rule tests in the Kramers-Kronig analysis of optical data: Applications to aluminum. *Physical Review B* 22: 1612.

The calculation of the second derivative of the dielectric function with inclusion of relativistic corrections has been carried out by Scandolo, Bassani and Lucarini; it is rather complex and will not be reported here (see Scandolo et al. (2001)). When the result is substituted in the frequency dependence (41) its asymptotic behavior is obtained, and the sum rules can be derived in the usual way with spatial dispersion and relativistic corrections. The sum rule on the real part of the susceptibility is unchanged, and gives zero. That on the imaginary part is modified by a contribution which depends on the expectation value of the kinetic energy of the electrons on the total ground state of the system $T_0 = \langle 0 | \frac{1}{2}mv^2 | 0 \rangle$. The result is

$$\int_0^\infty \omega' \epsilon_2(\omega') d\omega' = \frac{\pi}{2} \omega_p^2 \left(1 - \frac{2}{3} \frac{T_0}{mc^2} \right). \quad (42)$$

This correction is very small, of the order of $\approx 10^{-3}$ in Al, where tests of sum rule have been made, but it may be easily detected in heavy materials using synchrotron radiation up to very high frequencies.

General description of nonlinear optical functions

Nonlinear optics includes a number of phenomena which are of great interest and have become of very common use with the availability of intense laser radiation (Blombergen, 1965; Shen, 1980; Boyd, 1992). Among them multiple-frequency generation, dynamic Stark effect, two-photon absorption, stimulated Raman absorption, electromagnetically induced transparency. All these phenomena must obey the causality principle, and consequently Kramers-Kronig (KK) relations and optical sum rules may be obtained for nonlinear optical phenomena in a way totally analogous to that used in linear optics as described above (Bassani and Scandolo, 1991; Lucarini et al., 2003, 2005).

One may start with the definition of the n -th order polarization of a medium, expressed in terms of the external electric fields as

$$P^{(n)}(t) = \int_{-\infty}^{+\infty} dt_1 \dots dt_n G^{(n)}(t_1, \dots, t_n) E_1(t - t_1) \dots E_n(t - t_n), \quad (43)$$

where the response function is symmetric under an exchange of variables, and satisfies the time causality condition

$$G^{(n)}(t_1, t_2, \dots, t_n) = 0 \quad \text{if any } t_i < 0. \quad (44)$$

The electric fields are taken to be sinusoidal with given frequencies, of the form

$$\vec{E}_n(\tau) = E_n(\omega_n) \exp[-i\omega_n\tau] + E_n^*(\omega_n) \exp[i\omega_n\tau], \quad (45)$$

where by convention the first term gives contributions to the susceptibility of argument ω_n and the second of argument $-\omega_n$.

Taking the Fourier transform of the polarization, one obtains the expression for the frequency component of the polarizability at any order

$$P^{(n)}(\omega) = \chi^{(n)}(\omega_1, \dots, \omega_n) E_1(\omega_1) \dots E_n(\omega_n) \delta[\omega - (\omega_1 + \dots + \omega_n)], \quad (46)$$

where $\chi^{(n)}(\omega_1, \dots, \omega_n)$ is defined as the Fourier transform of $G^{(n)}(t_1, \dots, t_n)$,

$$\chi^{(n)}(\omega_1, \dots, \omega_n) = \int_0^\infty dt_1 \dots \int_0^\infty dt_n \exp[i(\omega_1 t_1 + \dots + \omega_n t_n)] G^{(n)}(t_1, \dots, t_n), \quad (47)$$

and the symmetry in time implies that it is symmetric for the exchange of frequencies. The reality of $G_n^{(n)}(t_1, \dots, t_n)$, implies also

$$\chi^{(n)}(-\omega_1, \dots, -\omega_n) = \chi^{(n)*}(\omega_1, \dots, \omega_n). \quad (48)$$

If the fields are not sinusoidal one can expand them in their Fourier components of type (45) and the sum over the frequencies $\omega_1, \dots, \omega_n$ must be considered, with the appropriate field amplitudes.

It can be observed that in the nonlinear case the polarization is obtained by multiplying the n -th order susceptibility by all the field amplitudes, so that its dimensionality depends on the order considered. The susceptibilities $\chi^{(n)}(\omega_1, \dots, \omega_n)$ contain all the optical properties of the system to all orders, in the presence of a number of radiation beams.

The various terms of the susceptibilities to any order correspond to particular phenomena, and specific expressions can be obtained in each case, but, since one is interested in the general properties, only the asymptotic behavior for $\omega \rightarrow \infty$, or $t \rightarrow 0^+$ is relevant. A simple way to obtain it in the classical model is to extend the Lorentz oscillator scheme described in the linear case by adding to the harmonic contribution a potential with all the anharmonic terms, and solving the resulting equations of motion by iteration. A more precise quantum-mechanical expression can be used, which is an extension of equation (30) given above for the linear case

$$G^{(n)}(t_1, \dots, t_n) = \frac{1}{n!(i\hbar)^n} \sum T(1, \dots, n) \{ \text{Tr}[P(-t_1), \dots, P(-t_n), \mathcal{Q}_0] P \}, \quad (49)$$

where T denotes the time ordering operator, and P is the dipole moment operator, whose time dependence is expressed in the interaction representation in terms of the Hamiltonian H_0 .

Since dissipation is proportional to the time average

$$\left\langle \frac{dP(t)}{dt} E(t) \right\rangle, \quad (50)$$

it vanishes when the fields and the polarization oscillate at different frequencies.

At different orders, different effects appear considering all possible frequencies of the external electromagnetic fields. It is convenient to indicate the frequency of $P(\omega)$ and those of the external fields explicitly in the susceptibilities.

In second order one has with a single very intense beam the second-harmonic generation from $\chi^{(2)}(2\omega_1; \omega_1, \omega_1)$ and optical rectification from $\chi^{(2)}(0; \omega_1, -\omega_1)$; at higher orders we have higher-harmonic generation $\chi^{(n)}(n\omega_1; \omega_1, \dots, \omega_1)$. With different beams, in second order one has the sum and difference frequency generation $\chi^{(2)}(\omega_1 + \omega_2; \omega_1, \omega_2)$ and $\chi^{(2)}(\omega_1 - \omega_2; \omega_1, -\omega_2)$ and at higher order all possible sums and differences. These do not give any absorption because the polarization frequency and the field frequency are different; the real and imaginary parts define in this case the phases of the susceptibility amplitudes.

In third order and at higher odd orders an important contribution to the susceptibility corresponds to the so-called pump and probe experiments, where one detects the dispersion and the absorption of a weak probe beam of frequency ω , in the presence of an intense beam of frequency ω_2 . The nonlinear susceptibility $\chi^{(2n+1)}$ is proportional to the intensity of the pump beam at the n -th power. The susceptibility $\chi^{(3)}(\omega; \omega, \omega_2, -\omega_2)$ and more generally $\chi^{(2n+1)}(\omega; \omega, \omega_2, -\omega_2, \dots)$ contains a dynamical Stark effect when ω is close to a first-order resonance, a two-photon absorption when $\omega + \omega_2$ is close to a possible transition frequency, the stimulated Raman effect when $\omega - \omega_2$ is close to a transition frequency. In the pump and probe case, with a three-level system one also obtains, under particular conditions, a coherent interference effect which produces electromagnetically induced transparency (EIT) inside the first-order absorption line.

To consider the general properties related to pump and probe nonlinear dispersive-dissipative effects, one can study the dielectric function which is the sum of the linear contribution and all odd nonlinear contributions with final frequency ω of the probe field

$$\varepsilon_{\text{tot}}(\omega; \omega_2, E_2(\omega_2)) = \varepsilon^L(\omega) + \varepsilon^{\text{NL}}(\omega; \omega_2, E_2(\omega_2)) = 1 + 4\pi \sum_{n \text{ odd}} a_n \chi^{(n)}(\omega; \omega, \omega_2, -\omega_2, \dots, \omega_2, -\omega_2) E^{n-1}(\omega_2), \quad (51)$$

where

$$a_n = \frac{1}{2^{n-1}} \frac{(n-1)!}{\left(\frac{n-1}{2}\right)! \left(\frac{n-1}{2}\right)!}, \quad (52)$$

The nonlinear contribution is given by the sum of the terms with $n > 1$, and the numerical factor is given by the invariance of the susceptibility for permutation of the frequencies. The most important nonlinear term is clearly $\chi^{(3)}(\omega; \omega, \omega_2, -\omega_2)$.

Kramers-Kronig relations and sum rules in non-linear optics

The analytic properties of the nonlinear optical susceptibilities can be examined in increasing order, and a number of sum rules can be obtained easily, when KK relations hold, by extending the procedure given for the linear case.

A first property follows immediately from causality due to Titchmarsh theorem: the susceptibility is holomorphic in the upper half of the complex plane associated with one of the frequency variables when all the others are kept fixed. A second more general theorem due to causality was derived by Scandolo; the nonlinear susceptibility is holomorphic in the upper half-plane of any straight line with positive slope in the frequency space of all the ω_i . This holds of course also by taking the line with zero slope along a given axis, provided the other values can be kept fixed.

From the above results one can see immediately that KK relations can be established in most cases previously described, in second and higher harmonic generation along ω_1 , as well as in pump and probe experiment along ω , keeping ω_2 fixed. They do not apply in optical rectification, because any straight line in the space $\omega, \omega_2 = -\omega$ cannot have positive slope; they do not apply also for $\chi^{(3)}(\omega_1; \omega_1, -\omega_1, \omega_1)$, when only one beam is present. The asymptotic behavior of the nonlinear susceptibilities is in general much faster than in the linear case, so that one may consider all integrable products of the type $\omega^k \chi^{(n)}(\omega)$, along the line of positive slope which is considered, and thus obtain a number of KK relations. From them, (using the superconvergence theorem as shown in the linear case) the asymptotic behavior of the real and the imaginary part of the susceptibility can be obtained in terms of their moments (integral of powers of the frequency times the susceptibility), up to a given value, above which the integral does not converge. Comparison of such asymptotic behavior of the susceptibility with the behavior obtained from specific calculations gives a number of new sum rules for the nonlinear susceptibilities considered.

Harmonic generation

As a first example let us consider the second-harmonic generation. The asymptotic behavior of $\chi^{(2)}(2\omega, \omega, \omega)$ as $\omega \rightarrow \infty$ can be obtained easily from the anharmonic oscillator model or equivalently from quantum theory. They give similar results, provided the appropriate third-order derivative $\frac{\partial^3 V(x)}{\partial x^3}$ for x-polarized radiation is substituted in the quantum theory by its expectation value on the ground-state wave function. The following second-harmonic asymptotic behavior obtains

$$\chi_{\omega \rightarrow \infty}^{(2)}(2\omega; \omega, \omega) = + \frac{1}{2!} \frac{e^3}{m^2} \left[\frac{\partial^3 V(x)}{\partial x^3} \right]_0 \frac{1}{4} \frac{1}{\omega^6} + o(\omega^{-6}), \quad (53)$$

where the potential term is given by the anharmonic coefficient in the extended Lorentz model, and by its expectation value on the ground state in the quantum mechanical approach. In the presence of the polarized beams of the same frequency the derivatives can refer to the polarization directions of the fields and to the polarizations directions of $\vec{P}$, so that a third-order tensor component is defined. As a consequence of the asymptotic behavior (53) one obtains three independent KK relations, one for $\chi^{(2)}(2\omega; \omega, \omega)$, one for $\omega^2 \chi^{(2)}$, and another one for $\omega^4 \chi^{(2)}$. They can be summarized as follows in terms of their real and imaginary part χ_1, χ_2 :

$$\begin{aligned} \omega^{2\alpha} \chi_1^{(2)}(2\omega; \omega, \omega) &= \frac{2}{\pi} \int_0^\infty \frac{\omega'^{2\alpha+1} \chi_2^{(2)}(2\omega'; \omega', \omega')}{\omega'^2 - \omega^2} d\omega', \\ \omega^{2\alpha-1} \chi_2^{(2)}(2\omega; \omega, \omega) &= -\frac{2}{\pi} \int_0^\infty \frac{\omega'^{2\alpha} \chi_1^{(2)}(2\omega'; \omega', \omega')}{\omega'^2 - \omega^2} d\omega', \end{aligned} \quad (54)$$

with $0 \leq \alpha \leq 2$. By comparing the asymptotic behavior obtained from the above KK relations, via the superconvergence theorem, which amounts to neglecting ω'^2 in the denominator of (54), with the one given above, (53), one obtains six sum rules which can be summarized as follows:

$$\begin{aligned} \int_0^\infty \omega^{2\alpha} \chi_1^{(2)}(2\omega; \omega, \omega) d\omega &= 0, \quad \text{for } \alpha = 0, 1, 2, \\ \int_0^\infty \omega^{2\alpha+1} \chi_2^{(2)}(2\omega; \omega, \omega) d\omega &= 0, \quad \text{for } \alpha = 0, 1, \\ \int_0^\infty \omega^5 \chi_2^{(2)}(2\omega; \omega, \omega) d\omega &= -\frac{\pi}{2} \cdot \frac{e^3}{8} m^{-2} \mathcal{Q} \left[\frac{\partial^3 V}{\partial x^3} \right]_0. \end{aligned} \quad (55)$$

The procedure given has been extended to higher harmonics and gives a large number of sum rules. All integrals of even moments of the real part of the susceptibility vanish up to the $2n$ moment, and all odd moments of the imaginary part of the susceptibility vanish, with the exception of the $2n + 1$ moment.

Pump and probe

Now, consider the pump and probe experiments, where the response to a beam of frequency ω is studied in the presence of an intense beam of frequency ω_2 . The nonlinear contributions due to the probe beam alone are neglected, and the nonlinear susceptibility $\chi^{(3)}(\omega; \omega, \omega_2, -\omega_2)$, or more generally $\chi^{(2l+1)}(\omega; \omega, \omega_2, -\omega_2, \dots, \omega_2)$ for a very intense pump beam is considered. The asymptotic behavior can be obtained also in this case from the anharmonic oscillator model, or from the quantum-mechanical approach by using the Fourier transform (47) of the response function (49) for $t_1 \rightarrow 0^+$. One can show that the asymptotic behavior of the nonlinear susceptibility is

$$\tilde{\chi}^{\text{NL}} = -\frac{C}{\omega^4} + o(\omega^{-4}), \quad (56)$$

with

$$C = - \sum_{n \text{ odd} > 1} \frac{a_n e^2}{n! (-i\hbar)^{n-1} m^2} E_2^{n-1}(\omega_2) \int dt_2 \dots \int dt_n \cdot \exp[-i(\omega_2 t_2 - \omega_2 t_n)] \text{Tr} \left\{ \frac{\partial^2 V}{\partial x^2} \sum_{p'} T(2 \dots n) [P(-t_2) \dots P(-t_n), \mathbb{Q}_0] \right\} \quad (57)$$

and

$$a_n = \frac{1}{2^{n-1}} \frac{(n-1)!}{\left(\frac{n-1}{2}\right)! \left(\frac{n-1}{2}\right)!}.$$

From this it can be seen that two KK relations follow. One is the same as the linear KK relations and applies to $\chi^{\text{NL}}(\omega; \omega_2, E_2)$. The other typical of nonlinear contribution for the probe-pump situation applies to $\omega^2 \chi^{\text{NL}}(\omega; \omega_2, E_2)$

$$\begin{aligned} \omega^2 \chi_1^{\text{NL}}(\omega; \omega_2, E_2) &= \frac{2}{\pi} f d\omega' \frac{\omega'^3 \chi_2^{\text{NL}}(\omega'; \omega_2, E_2)}{\omega'^2 - \omega^2}, \\ \omega^2 \chi_2^{\text{NL}}(\omega; \omega_2, E_2) &= \frac{2\omega}{\pi} f d\omega' \frac{\omega'^2 \chi_1^{\text{NL}}(\omega'; \omega_2, E_2)}{\omega'^2 - \omega^2}. \end{aligned} \quad (58)$$

This relation, appropriate to the nonlinear contribution, can be used to relate dispersive to dissipative nonlinear phenomena, as well as the original KK relation.

From the asymptotic expansion (56) and the two KK relations obtained, one can derive four sum rules for the nonlinear susceptibility, by following the usual procedure of imposing that their asymptotic behaviors coincide. They are the following:

$$\begin{aligned} \int_0^\infty \chi_1^{\text{NL}}(\omega; \omega_2, E(\omega_2)) d\omega &= 0, \\ \int_0^\infty \omega_2^{\text{NL}}(\omega; \omega_2, E(\omega_2)) d\omega &= 0, \\ \int_0^\infty \omega^2 \chi_1^{\text{NL}}(\omega; \omega_2, E(\omega_2)) d\omega &= 0, \\ \int_0^\infty \omega^3 \chi_2^{\text{NL}}(\omega; \omega_2, E(\omega_2)) d\omega &= C \frac{\pi}{2}, \end{aligned} \quad (59)$$

where C is given by (57). The first two are analogous to the linear sum rules whose validity is thus extended to the optical response to all orders in the presence of a pump beam. The last two are typical of the nonlinear susceptibility. The last one in particular gives a measure of the strength of the nonlinear response through the value of the constant C .

Another simple sum rule gives immediately the nonlinear contribution of the pump field to the static susceptibility (limit $\omega \rightarrow 0$ in the KK dispersion relations)

$$\varepsilon^{\text{NL}}(0; \omega_2, E(\omega_2)) = \frac{2}{\pi} \int_0^\infty d\omega' \frac{\chi_2^{\text{NL}}(\omega'; \omega_2, E(\omega_2))}{\omega'}. \quad (60)$$

Analogous sum rules can be obtained for all the nonlinear optical functions related to the susceptibility, as in the linear case.

Examples and applications to nonlinear processes

The anharmonic oscillator

One can display the relevance of the above-described sum rules by considering the simple, but physically significant anharmonic-oscillator case.

Fig. 3 Anharmonic part of the optical response of the nonlinear oscillator. From Bassani F (2005b) Sum Rules and Kramers-Kronig Relations in Nonlinear Optics. ECMP 1st edn.

By solving the equation of motion with the probe frequency ω and the pump ω_2 one obtains in third order the anharmonic contribution $\chi^{(3)}(\omega; \omega, \omega_2, -\omega_2)$. The result is displayed in Fig. 3 as a function of the frequency of the probe beam ω .

One can observe the modification of the absorption near the resonance ω_0 which is a dynamic Stark effect with a positive and a negative contribution; also a peak is present in correspondence to a two-photon absorption at $\omega_0 - \omega_2$ and another peak due to stimulated Raman absorption at $\omega = \omega_0 + \omega_2$. The sum rules (59) are all verified, but include contributions from all these effects and cannot be referred to a particular phenomenon on its own.

Analogous results are obtained from a quantum-mechanical study of the oscillator, where however differences are found from the classical model in the nonlinear optical functions.

Second-harmonic generation

A further example of how the sum rules can be used to verify detailed theories, and to implement useful simplified models can be seen as an application to second-harmonic generation.

The quantum-mechanical calculation of $\chi^{(2)}(2\omega; \omega, \omega)$ is very complicated, because a knowledge of all excited states and a double summation involving all dipole matrix elements between them is required. One can set up a simple model by considering an expansion about the main poles at ω_0 and $\omega_0/2$, ω_0 being the average frequency of the direct interband transitions in the semiconductors, which is also responsible for the static linear dielectric constant. Thus one writes

$$\begin{aligned} \chi^{(2)}(2\omega; \omega, \omega) = & \frac{f_1}{\omega - \omega_0 + i\epsilon^+} + \frac{f_2}{(2\omega - \omega_0) + i\epsilon^+} + \\ & + \frac{f_3}{(\omega - \omega_0 + i\epsilon^+)^2} + \text{c.c.}(\omega \rightarrow -\omega), \end{aligned} \quad (61)$$

where ϵ^+ is a positive infinitesimal which can be set to zero. The coefficients f_i give the strength of the poles and substitute the detailed double sum of dipole matrix elements. Imposing the sum rules, one can obtain expressions for all the coefficient f_i , in terms of the quantity C which appears in the 5th moment sum rule (see eq. (59)).

Taking the limit $\epsilon^+ \rightarrow 0$, and expressing the first-order susceptibility in terms of the average transition frequency to the conduction band as

$$\chi = \frac{qe_1^2}{m(\omega_0^2 - \omega^2)}, \quad (62)$$

one obtains Miller's empirical rule

Fig. 4 Second order static susceptibility for some semiconductors. Abscissae: theoretical calculations in units of 10^{-8} esu; ordinate: experimental data squares in units of 10^{-8} esu. Reproduced with permission from Scandolo S and Bassani F (1995) Miller's rules and the static limit for second harmonic generation. *Physical Review B* 51: 6928.

$$\chi_{ijk}^{(2)}(2\omega; \omega, \omega) = \Delta_{ijk} \chi_{ii}^{(1)}(2\omega) \chi_{jj}^{(1)}(\omega) \chi_{kk}^{(1)}(\omega), \quad (63)$$

where Miller's empirical constant Δ is given by

$$\Delta_{ijk} = -\frac{1}{2e^3 Q^2} \left\langle \frac{\partial^3 V}{\partial r_i \partial r_j \partial r_k} \right\rangle_0. \quad (64)$$

This can be easily computed for crystals from pseudopotential theory, by means of the values of the pseudopotential parameters used in the energy band calculations. One can thus compute the static limit in a number of semiconductors and obtain values of $\chi^{(2)}(0,0)$ in good agreement with experiment, as shown in Fig. 4 (Scandolo and Bassani, 1995).

Similar result can be obtained for third- and higher-order harmonic generation processes.

Data analysis

The above described sum rules and KK relations can be also used to complete the experimental data available by imposing that they verify such general properties. This is particularly useful in nonlinear optics, where results on a limited frequency range are experimentally available, and only at a few fixed frequencies both real and imaginary nonlinear susceptibilities are measured. For this, refer to the detailed analysis by Lucarini et al. (Lucarini et al., 2003, 2005).

Conclusion

It has been shown that the principle of time causality implies a number of Kramers-Krönig relations between the real and the imaginary part of the linear and nonlinear susceptibilities and of all optical response functions. From them a variety of sum rules can be obtained for the frequency moments of the real and the imaginary parts of the linear and nonlinear susceptibilities.

The dispersion relations and the sum rules are shown to be useful to interpret experimental data and to verify the accuracy of theoretical models.

Abstract

An overview of the optical spectra of semiconductors is presented illustrating their relation to the critical points of the electronic band structure and the direct vs indirect character of the fundamental gap. The basic properties of the dielectric function are described. Direct interband transitions, including exciton and polariton features, are considered as well as indirect phonon assisted transitions. Illustrative absorption and reflectivity spectra along with modulation spectroscopy results are presented. A few examples of novel light-emitting semiconducting materials are finally discussed.

Key points

- The role of the dielectric function in the theoretical interpretation of the optical properties is discussed.
- Semiconductor spectroscopy is related to the electronic band structure.
- Modulation spectroscopy is discussed as a tool to determine the critical points in the Brillouin zone.
- Direct and indirect interband transitions are considered.
- Exciton and polaritons are introduced.

Introduction

Even though the paramount role of semiconductors, and of silicon above all, in modern technology is mainly due to their use in electronic microdevices, the optical properties of these materials are also of great interest. In particular, many applications of semiconductors are based on optoelectronic effects: the transformation of light in electrical current (photovoltaic devices), and the transformation of electrical current in light (semiconductor light emitting diodes and lasers), the choice of device architectures being greatly expanded by the band engineering capabilities offered by heterostructures. Of course, the spectroscopy of semiconductors has been, and continues to be, a subject of crucial relevance also from the point of view of basic science as it allows a detailed study of the electronic structure of these materials (Bassani and Pastori Parravicini, 1975; Agranovich and Ginzburg, 1984; Cohen and Chelikowsky, 1988; Yu and Cardona, 1995).

In the following, we will concentrate mainly on bulk properties rather than on heterostructures, and focus on the optical part of the spectrum due to interband electronic excitations, possibly assisted by phonon participation (La Rocca, 2005). After discussing general concepts related to the linear optical response functions, the corresponding absorption spectra will be considered as they are much less sensitive than luminescence to extrinsic effects. Excitonic and polaritonic phenomena will also be touched upon and the role of external perturbations on the optical properties will be discussed (modulation spectroscopy). Finally, emerging light-emitting semiconductor materials will be considered.

The dielectric function

Semiconductors are characterized by an energy gap of the order of the electronvolt (see Table 1), and correspondingly by an absorption edge in the near infrared or in the visible below which they are nearly transparent and above which they are almost opaque. Actually, a direct measurement of the absorption is rather difficult as it is so strong when the frequency is higher than the

Table 1 Energy gap values (in eV) of cubic semiconductors at room temperature

	<i>AlSb</i> (i)	<i>CdTe</i> (d)	<i>GaAs</i> (d)	<i>GaP</i> (i)	<i>GaSb</i> (d)

threshold frequency that no radiation goes through the semiconductor, but for extremely thin layers. This difficulty can be overcome when the optical quality of the surfaces makes it possible to measure by ellipsometry both the real and the imaginary part of the dielectric function as a function of the light frequency. Alternatively, a measurement of the reflectivity over a large frequency range with sufficient accuracy and the application of the Kramers-Kronig relations allow to determine the real and the imaginary part of the reflection coefficient. From this the dispersion and the absorption can be obtained, establishing the bases for the experimental determination of the optical response of semiconductors and of its theoretical interpretation in terms of the electronic band structure.

We recall that the normal incidence reflection coefficient, defined as the ratio between the electric field of reflected and incident wave, is related to the complex index of refraction $\tilde{n}$ by the Fresnel relation

$$r = \frac{E_r}{E_i} = \frac{\tilde{n} - 1}{\tilde{n} + 1} = |r|e^{i\theta}, \quad (1)$$

and taking the logarithm:

$$\log r = \log |r| + i\theta. \quad (2)$$

Since this is an analytic function of the frequency ω in the upper complex plane $\omega + i\eta$, the following Kramers-Kronig relation holds true

$$\theta(\omega) = -\frac{2\omega}{\pi} \mathcal{P} \int_0^\infty \frac{\log |r(\omega')|}{\omega'^2 - \omega^2} d\omega', \quad (3)$$

and from the measured reflectivity $|r(\omega')|^2$, $\theta(\omega)$ can be obtained, and consequently the real and imaginary parts of $\tilde{n} = n + ik$ can be derived from (1).

This amounts to the knowledge of dispersion and absorption since the complex dielectric function is related to $\tilde{n}$ by

$$\tilde{\epsilon} = \epsilon_1 + i\epsilon_2 = \tilde{n}^2. \quad (4)$$

The dissipation is related to the imaginary parts, since the absorption coefficient is given by

$$\alpha(\omega) = \frac{2k\omega}{c} = \frac{\epsilon_2\omega}{nc}, \quad (5)$$

while the real part $n(\omega)$ gives the dispersion.

To relate the measured optical constants to the electronic structure, we must consider the interaction between the electromagnetic radiation and the electrons which can be expressed in the Coulomb gauge by the minimal coupling Hamiltonian as

$$H' = \frac{|e|\hbar}{mc} \vec{A} \cdot \vec{p}, \quad (6)$$

where $\vec{A} = \vec{A}_0 e^{-i\omega t} + \vec{A}_0^* e^{i\omega t}$ denotes the vector potential (the contribution to H' proportional to A^2 being neglected) and the momentum operator $\vec{p}$ induces the transition between different electronic states. We recall that the transition probability per unit time between an occupied lower initial state $|i\rangle$ and an empty higher final state $|f\rangle$ is given by the Fermi golden rule

$$P_{i \rightarrow f}^{(1)} = \frac{2\pi}{\hbar} |\langle f | H' | i \rangle|^2 \delta(E_f - E_i - \hbar\omega). \quad (7)$$

In the case of semiconductors we must sum over all occupied initial states (valence bands) and empty final states (conduction bands) in the unit volume to compute the electromagnetic power dissipated at a given frequency

$$W(\omega) = \frac{1}{V} \sum_{i,f} \hbar\omega P_{i \rightarrow f}^{(1)}, \quad (8)$$

where V is the crystal volume. The absorption coefficient is by definition

$$\alpha(\omega) = \frac{\text{dissipated power per unit volume}}{\text{incoming flux}} = \frac{W(\omega)}{\left(\frac{cnE^2}{2\pi}\right)}. \quad (9)$$

The imaginary part of the dielectric function, rather than the absorption coefficient, can be directly calculated as it does not depend on the real part of the index of refraction. From the above expressions, we obtain for the dissipative function

$$\varepsilon_2(\omega) = \left(\frac{2\pi e}{m\omega}\right)^2 \sum_{c,v} \int \frac{d\vec{k}}{(2\pi)^3} \left| \langle \psi_{c\vec{k}} | \vec{p} | \psi_{v\vec{k}} \rangle \right|^2 \delta(E_c(\vec{k}) - E_v(\vec{k}) - \hbar\omega), \quad (10)$$

where the wavefunctions and their energies are given by a band structure calculation, the integration is over the first Brillouin zone and a factor of two assuming spin degeneracy has been included. Here, as the wavevector of light $2\pi/\lambda$ is much smaller than the size of the Brillouin zone π/l , being l the lattice constant, only allowed “vertical” transitions between electronic states having the same $\vec{k}$ have been considered.

The real part $\varepsilon_1(\omega)$ is then obtained from the Kramers-Kronig dispersion relation

$$\varepsilon_1(\omega) = 1 + \frac{2}{\pi} \mathcal{P} \int_0^\infty \frac{\omega' \varepsilon_2(\omega')}{\omega'^2 - \omega^2} d\omega' \quad (11)$$

and from the complex dielectric function the optical dispersion and absorption properties follow. We finally recall that since most semiconductors of interest (e.g., those in Table 1) are cubic their optical response is isotropic as assumed here.

Interband transitions

The optical absorption in crystals is mostly due to interband transitions, i.e. to the promotion of electrons from occupied valence bands to empty conduction bands. Because of the energy conserving δ -function in (10), a singular behavior of the response functions is obtained in the vicinity of the critical points of the Brillouin zone (Van Hove singularities), where for a given couple of conduction and valence bands

$$\vec{\nabla}_{\vec{k}}(E_c(\vec{k}) - E_v(\vec{k})) = 0. \quad (12)$$

In fact, near a critical point it is often a good approximation to consider the transition matrix element as a constant. Then, the integral in (10) is simply proportional to the joint density of states $J(\omega)$:

$$J(\omega) = \int \frac{d^3k}{(2\pi)^3} \delta(E_c(\vec{k}) - E_v(\vec{k}) - \hbar\omega) = \frac{2}{(2\pi)^3} \int_{S(\omega)} \frac{d^2k}{|\vec{\nabla}_{\vec{k}}(E_c(\vec{k}) - E_v(\vec{k}))|}, \quad (13)$$

where the two-dimensional integral is over a surface $S(\omega)$ in $\vec{k}$ -space for which $E_c(\vec{k}) - E_v(\vec{k}) = \hbar\omega$.

The location of critical points in the Brillouin zone is mainly (but not completely) determined by symmetry considerations. For cubic semiconductors, the points Γ , X , L and W in the Brillouin zone (see Fig. 1) are always critical points; other critical points usually occur along lines or planes of symmetry, but critical points at a generic wavevector $\vec{k}$ cannot be excluded. Van Hove

Fig. 2 Absorption edge of InSb. Based on NSM NSM Archive (2001) <http://www.ioffe.ru/SVA/NSM/Semicond/>

singularities have been found in the optical spectra of all semiconductors, and this has allowed the identification of the critical point transition peaks and the verification of the band structure.

A direct gap semiconductor is characterized by having both the conduction band minimum and the valence band maximum at the same wavevector $\vec{k}$ (typically the Γ point at $k = 0$). When the optical transition between them is allowed, the absorption edge at a frequency corresponding to the band gap E_g is due to the fact that the joint density of states vanishes for $\hbar\omega < E_g$ and increases sharply for $\hbar\omega \simeq E_g$. In particular, assuming a parabolic dispersion of the conduction and valence band states for $\hbar\omega \geq E_g$

$$J(\omega) \propto \sqrt{\hbar\omega - E_g}. \quad (14)$$

This result correctly describes the gross features of the absorption edge for allowed interband transitions in direct gap semiconductors. As an example, the absorption spectrum of InSb near its direct gap is shown in Fig. 2 (NSM Archive, 2001) exhibiting a well pronounced absorption edge and becoming opaque at frequencies $\hbar\omega > E_g$ with an absorption coefficient $\alpha \approx 10^4 \text{ cm}^{-1}$.

In Fig. 3 the entire experimental excitation spectrum of Ge (the lowest gap of which is indirect, see below) is compared to that computed as described above from a pioneering band structure calculation based on empirical pseudopotentials (Brust et al., 1962). In this classical example, not only have the critical points been identified, but also the full band structure has been put to test obtaining a satisfactory agreement with the measured data. From the calculation of the dipole matrix elements at all points of the Brillouin zone and for all possible transitions to higher conduction bands, it can be concluded that most of the absorption is due to transitions to the lowest empty conduction bands. This fact can also be proved by verifying the f -sum rule in the optical range

$$\int_0^{\omega_M} \omega \varepsilon_2(\omega) d\omega \simeq \frac{2\pi^2 e^2 n_{\text{eff}}}{m}, \quad (15)$$

where in this case the frequency ω_M is just above the spectrum in the visible region, and n_{eff} is about equal to the number of valence electrons which take part in the optical transitions (8 per unit cell in elemental semiconductors such as Ge).

Fig. 3 Imaginary part of the dielectric function of Ge: the solid line is experimental, the dashed one theoretical; optical transitions at critical points are identified. Reproduced with permission from Brust D, Phillips JC, Bassani F (1962) *Physical Review Letters* 9: 94.

Phonon-assisted transitions

Differently from the case of direct gap semiconductors such as GaAs and InSb, for Si and Ge while the top of the valence band is still at the center of the Brillouin zone (Γ point), the minimum of the conduction band occurs away from Γ (close to the X point along the Δ line in Si, at the L point in Ge). This has been clearly observed by cyclotron resonance experiments, but it also shows in the optical properties, because the electron-phonon interaction makes possible an optical transition between different points of the Brillouin zone, the missing (pseudo)momentum being provided by the phonon emitted or absorbed.

The probability of an indirect transition can be calculated in second order perturbation theory taking the perturbation interaction to be the sum of (6) and the electron-phonon interaction. Assuming constant matrix elements involving the states near the extrema which give the strongest contribution, one obtains

$$\varepsilon_2(\omega) \propto \left(n_{\vec{q}_0, \nu_0} + \frac{1}{2} \pm \frac{1}{2} \right) \iint \frac{2d\vec{k}_1 d\vec{k}_2}{(2\pi)^6} \delta \left(E_c \left(\vec{k}_1 \right) - E_v \left(\vec{k}_2 \right) \pm \hbar\omega_{\nu_0} \left(\vec{q}_0 \right) - \hbar\omega \right), \quad (16)$$

where $+$ ($-$) refers to creation (destruction) of a phonon of mode ν_0 with the wavevector $\vec{q}_0$ which connects the valence band maximum and the conduction band minimum.

The summation over the final electronic states above the edge ($\hbar\omega_0$) gives an energy dependence which is different from that of direct transitions, and precisely

$$\begin{aligned} \varepsilon_2(\omega) &= 0 \quad \text{when } \omega < \omega_0, \\ \varepsilon_2(\omega) &\propto (\omega - \omega_0)^2 \quad \text{when } \omega > \omega_0. \end{aligned}$$

Furthermore, different edges occur in correspondence to each phonon, and their values depend on the fact that the phonons are absorbed or emitted. At low temperature we can only create phonons, and consequently the edge occurs at higher energy

$$\hbar\omega_0 = E_g + \hbar\omega_{\nu_0} \left(\vec{q}_0 \right). \quad (18)$$

At higher temperature we can also absorb phonons, with a temperature dependent probability given by the Bose-Einstein factor, and the edge is shifted to lower energy

$$\hbar\omega_0 = E_g - \hbar\omega_{\nu_0} \left(\vec{q}_0 \right). \quad (19)$$

Fig. 4 Indirect absorption edge of Si at various temperatures. Based on NSM NSM Archive (2001) <http://www.ioffe.ru/SVA/NSM/Semicond/http://www.ioffe.ru/SVA/NSM/Semicond/>.

Indirect transitions are responsible for the weak absorption tail in Si and Ge, which reflects their conduction band structures. We show in Fig. 4 the absorption tail of Si; a fit to the profile of the indirect edge gives the frequency of the phonons which make the transition possible. At higher energies, when allowed direct transitions set in, the contribution of phonon-assisted indirect transitions to the absorption is negligible.

Excitons and polaritons

The discussion above neglects the attractive interaction between the electron promoted into the conduction band and the hole left behind in the valence band. However, their motion is correlated and, in particular, they can be bound into Wannier-Mott excitonic states with an energy below that of the single particle energy gap. Due to the large dielectric constant ($\epsilon_o \approx 10$) and the small reduced mass ($\mu = (m_e m_h)/(m_e + m_h) \approx 0.1 m_o$) typical of semiconductors, the exciton radius a_o is much larger than the lattice constant and the binding energy correspondingly small. In first approximation, an exciton turns out to be a “rescaled hydrogen atom” with binding energies depending only on the principal quantum number n

$$E_n = E_g - \frac{R^*}{n^2}; \quad R^* = \frac{\mu e^4}{2\epsilon_o^2 \hbar^2} = \frac{\hbar^2}{2\mu a_o^2} = \frac{e^2}{2\epsilon_o a_o}, \quad (20)$$

the exciton Bohr radius a_o being larger than 1 nm and the effective Rydberg R^* being typically of the order of 10 meV. Thus, the exciton absorption lines are typically prominent only at low temperatures, as shown for GaAs in Fig. 5.

The optical resonances below the band gap corresponding to the excitonic bound states can be described by the following complex dielectric constant

$$\epsilon(\omega) = \epsilon_b + \sum_n \frac{f_n}{(E_n/\hbar)^2 - \omega^2 - i\gamma_n \omega}, \quad (21)$$

where ϵ_b is a background dielectric constant, γ_n a phenomenological linewidth (e.g., due to phonon scattering), and the oscillator strength f_n is proportional to the square of the dipole matrix element between valence and conduction band extrema and inversely proportional to the exciton volume ($f_n \propto (na_o)^{-3}$).

Recently, Rydberg excitons levels with a very high principal quantum number n , akin to the Rydberg states of alkali atoms, have been observed: in Fig. 6 high resolution spectra of the yellow P exciton series in C_2O are shown exhibiting levels with n larger than 20 (Kazimierzczuk et al. (2014)). These excitons are truly *giant* extending over distances of the order of micrometers (much larger than the wavelength of the resonating light).

In correspondence to the excitonic resonances, when damping processes are small compared to the exciton-photon coupling, the electromagnetic waves propagating in the crystal hybridize with the exciton polarization giving rise to polariton states, i.e. the proper modes of Maxwell’s equations with the dielectric function given in (21). Their dispersion law is obtained from

$$\omega^2 = \frac{c^2}{\epsilon(\omega)} k^2, \quad (22)$$

Fig. 5 Excitonic absorption in GaAs, at room temperature the exciton peak is no longer observed. Based on NSM NSM Archive (2001) [http://www.ioffe.ru/SVA/NSM/Semicond/](http://www.ioffe.ru/SVA/NSM/Semicond/http://www.ioffe.ru/SVA/NSM/Semicond/).

giving for each excitonic resonance two branches (upper and lower polaritons) accompanied by a region of anomalous dispersion with a strongly reduced group velocity, as shown for GaAs in Fig. 7 (Ulbrich and Fehrenbach, 1979). In polar semiconductors, having strong infrared absorption lines due to optical phonons, phonon-polariton states are similarly formed.

Recently, the light-matter interaction in the strong coupling regime, particularly in planar semiconductor microcavities, have been extensively studied and the physics of interacting polaritons has revealed a number of fundamental many-body phenomena related to Bose-Einstein condensation and superfluidity (Carusotto and Ciuti (2013)).

Modulation spectroscopy

In an experimental spectrum, e.g., of the reflectivity, the van Hove singularities such as those shown in Fig. 3 might be difficult to identify. As an example, the optical reflectivity of Si in Fig. 8 exhibit quite a smooth behavior as a function of frequency. However, the possibility of employing a phase-sensitive detection technique in conjunction with a periodic modulation of an external perturbation improves, on the one hand, the signal to noise ratio by several orders of magnitude and, on the other hand, allows to enhance the sharp features of a spectrum with respect to a smoothly varying background. Modulation spectroscopy allows to directly measure derivative spectra showing very clearly the stronger singularities in the first (and higher order) derivatives of, say, the reflectivity as a function of frequency.

Thus, from the experimental point of view, much information on the properties of semiconductors can be obtained by measuring changes induced by externally applied perturbations. The latter can preserve the symmetry of the crystal (as for hydrostatic pressure or temperature changes) or lower it (as for uniaxial stress or electric and magnetic fields), in which case detailed information on the symmetry properties of the critical points of the electronic bands can be obtained. For instance, the reflectivity of Ge around 2.2 eV is dominated by interband transitions involving states along the Λ line in the Brillouin zone: uniaxial stress along the [001] direction does not split the degeneracy among the eight [111] valleys, whereas uniaxial stress along the [111] direction induces a difference between the two of them along the stress axis and the other six; in the latter case a polarization dependence of the reflectivity is observed.

One of the most common techniques of modulation spectroscopy is electroreflectance, in which the reflectivity is measured while applying an AC electric field parallel or perpendicular to the sample surface. The changes in optical constants measured by electroreflectance modulation spectroscopy have a very simple interpretation in the regime of low applied fields. In this case, as shown in Fig. 9 (Aspnes, 1972), the spectra are simply proportional to the third derivative of the respective optical constant with respect to frequency according to

$$\Delta\epsilon(\omega) \propto \frac{e^2 F^2}{\mu \hbar} \frac{1}{\omega^2} \frac{d^3}{d\omega^3} (\omega^2 \epsilon(\omega)), \quad (23)$$

where F is the electric field and μ the reduced mass of the relevant interband transition. The electroreflectance spectra (Fig. 9a) show much sharper features than those obtained by ellipsometry (Fig. 9c).

Fig. 8 Reflectivity spectrum of Si: dashed line is experiment, solid line is theory, based on an empirical pseudopotential band structure calculation. Based on NSM Archive (2001) [http://www.ioffe.ru/SVA/NSM/Semicond/](http://www.ioffe.ru/SVA/NSM/Semicond/http://www.ioffe.ru/SVA/NSM/Semicond/).

Novel light emitting materials

Semiconductors are a key class of materials from the technological viewpoint, with silicon playing a paramount role in the electronic industry. However, for optoelectronic applications and lasing in particular, silicon is hampered by the fact that its fundamental gap is indirect. Thus, a long standing goal in this research field is finding a good light-emitting material to be integrated on silicon. Substantial progress has been made with on-chip materials based on porous Si, Ge and SiGe alloys or also III–V semiconductors (Zhou et al., 2015). More recently, a strategy based on hexagonal Ge (2H–Ge) has been successfully pursued. Differently from the ordinary cubic Ge (c-Ge), 2H–Ge has a direct gap which can be seen as the result of folding the L point conduction band minimum of c-Ge to the Γ point. Most importantly, Si can be alloyed into 2H–Ge to form 2H– $\text{Si}_y\text{Ge}_{(1-y)}$ which for $y < 0.35$ maintains a direct gap tunable within the energy 0.3–0.7 eV. This has been experimentally observed (Fadaly et al., 2020) in quantum wires of 2H– $\text{Si}_y\text{Ge}_{(1-y)}$ as shown in Fig. 10.

Following the discovery of graphene, which is gapless, many monolayer thick materials have been studied including elemental semiconductor ones with direct gaps in the optical range such as phosphorene ($E_g \sim 2$ eV), i.e. a single layer of black phosphorous which in the bulk has a small band gap ($E_g \sim 0.3$ eV). A particularly interesting family of 2D semiconducting compounds is that of transition metal dichalcogenides (TMD) in which the character of the gap changes from indirect to direct going from a multilayer down to a monolayer thickness. In the monolayer limit, their direct gaps cover a range of energies: MoTe_2 ($E_g \sim 1.1$ eV), MoSe_2 ($E_g \sim 1.6$ eV), WSe_2 ($E_g \sim 1.7$ eV), MoS_2 ($E_g \sim 1.9$ eV), WS_2 ($E_g \sim 2.0$ eV). Their absorption spectra at the fundamental gap show pronounced exciton resonances as shown in Fig. 11 for MoS_2 (Mak et al., 2010) where the A and B exciton peaks correspond to transitions from the spin-orbit split valence band to the conduction band.

Conclusion

An overview of semiconductor optics has been presented focusing on the basic principles of the field and illustrating them via a variety of examples mainly based on traditional bulk materials. The study of their optical properties has played a crucial role in the understanding of the electronic structure of this important class of solids. While the optical properties of the main bulk semiconductors have been established for long, the current research in the field is mainly driven by the fundamental interest in complex physical phenomena as well as by the technological need for new materials and architectures for optoelectronic applications.

Abstract

Two-dimensional graphene-like materials with honeycomb crystal structure have non-trivial topological properties, which are characterized in terms of accumulation of topological phase of the Bloch wave functions and the phase of the interband dipole matrix elements when an electron is transferred in the reciprocal space. One of the natural ways to probe these topological properties is to apply a strong and short optical pulse, which induces the transfer of electrons in the reciprocal space over a large distance. In such pulses, the nontrivial topology of the graphene-like systems results in two phenomena. One is due to the interference effect in the interband electron dynamics, which results in appearance of interference fringes in the conduction band population distribution in the reciprocal space. This effect is realized in the graphene-like systems with small bandgap. Another phenomenon is related to the effect of topological resonance, which is the cancellation of the dynamic phase by the accumulated topological phase. The topological resonance is realized only in graphene-like systems with broken inversion symmetry and results in ultrafast valley polarization if a circular pulse is applied to the system.

Key points

- Two dimensional graphene-like materials, for example, pristine graphene and transition-metal dichalcogenide monolayers have honeycomb crystal structure with nontrivial topological properties.
- The topology is characterized in terms of intraband and interband Berry connections.
- Topological properties can be probed by femtosecond long and ultrastrong optical pulses.
- For semimetal graphene-like materials, which have an inversion symmetry, the optical pulse results in interference pattern in the conduction band population distribution in the reciprocal space.
- For semiconductor graphene-like materials, for which the inversion symmetry is broken, the topological resonance can be observed in the ultrafast electron dynamics
- The topological resonance occurs due to cancellation of the dynamic phase by the accumulated topological phase.
- For a circularly polarized pulse, the topological resonance results in ultrafast valley polarization of graphene-like semiconductor systems.

Introduction

Short and strong optical pulses with the duration of a few femtoseconds and the amplitude of around $1 \text{ V/\AA}$ can strongly modify both optical and transport properties of solids and have extensively used to probe and control the electron systems in solids (Apalkov and Stockman, 2012; Gruber et al., 2016; Heide et al., 2018, 2019; Higuchi et al., 2017; Kaiser et al., 2000; Liu et al., 2017; Mashiko et al., 2018; Motlagh et al., 2017, 2018; Nematollahi et al., 2019; Schiffrin et al., 2012; Shin et al., 2018; Sun et al., 2012; You et al., 2017). Such pulses produce strong interband mixing, which results highly non-perturbative electron dynamics. Such nonlinear dynamics results, for example, in metallization of dielectrics when the conductance of a dielectric solid increases by 18 orders of magnitude during a femtosecond-long pulse (Schiffrin et al., 2012). If the band gap of a solid is larger than the frequency of the pulse then such strongly nonlinear electron dynamics is also highly reversible, i.e., the electron system returns to its initial state after the pulse.

In addition to strong interband mixing, an ultrastrong optical pulse also results in long electron excursion in the reciprocal space. During the pulse an electron can propagate through almost the entire Brillouin zone. In topological materials, during such transfer the electron accumulates a topological phase, which can interfere with optically-induced interband dynamics and can affect both the transport and optical properties of topological materials (Oliaei Motlagh et al., 2018, 2019a). In this relation, the interaction of topological materials with strong optical pulses opens unique possibility to probe nontrivial topologically induced effects in solids.

In solids, there is a natural way to define nontrivial topological properties through accumulation of the phase of the Bloch wavefunctions when an electron is transferred through the reciprocal space. This phase which is called the geometric or Berry phase, determines both the local topological properties and the global topological charge of solid systems (Xiao et al., 2010). Two-dimensional topological systems that are based on the honeycomb crystal structure include such materials as pristine graphene, silicene, germanene, and transition metal dichalcogenide (TMDC) monolayers. The honeycomb crystal structure has two sublattices, A and B , while in the reciprocal space there are two valleys, K and K' , connected by the time reversal symmetry. The valleys are also called the Dirac points. For pristine graphene, which has an inversion symmetry, two sublattices A and B are equivalent and graphene is a semimetal with zero bandgap. In this case, near the Dirac points, the electrons are described by an effective massless Dirac Hamiltonian. If the inversion symmetry of graphene-like materials is broken, i.e., the sublattices A and B are not equivalent, then the system becomes a semiconductor with a finite bandgap. Among such gapped materials, TMDC monolayers with the bandgap of 1.1–2.1 eV (Conley et al., 2013; Jiang, 2015; Mak et al., 2010; Novoselov et al., 2016; Wang et al., 2012; Xiao et al., 2012) play a special role.

The TMDCs are composed of transition metals such as Mo, W, Ta, Re, Nb, or Zr, and chalcogens such as S, Se, or Te. They are usually denoted as MX_2 where M and X stand for the transition metal and the chalcogen, respectively. TMDCs are layered crystals with in-plane strong covalent bond and out-of-plane weak Van der Waals coupling that allows to isolate monolayers (Novoselov et al., 2016). TMDC monolayers are stable, and unlike the corresponding bulk solids, which are indirect semiconductors, these are direct semiconductors. This property has been proved to be tremendously useful in optoelectronics applications.

Similar to graphene, TMDC monolayers have honeycomb crystal structure with two triangular sublattices A and B (Geim and Novoselov, 2007), where each site of sublattice A is occupied by one metal atom, while each site of sublattice B is occupied by two chalcogen atoms per site (Liu et al., 2013). Thus, the inversion symmetry is intrinsically broken, which opens a finite bandgap at the Dirac points, i.e., at the two valleys K and K' . The degeneracy of the K - and K' -valleys is still protected by the time reversal symmetry (Geim and Novoselov, 2007).

The topological properties of solids are defined in terms of accumulation of the phase of the Bloch wave functions while an electron is transferred in the reciprocal space (Xiao et al., 2010). Mathematically, the topology of solids can be also described in terms of intraband and interband Berry connections. Introducing the lattice-periodic Bloch functions $\Psi_k^{(\alpha)}$, where α is the corresponding energy band, i.e., the conduction and valence bands, one can define the intraband

$$\mathcal{A}^{\alpha\alpha}(\mathbf{k}) = \left\langle \Psi_k^{(\alpha)} \left| i \frac{\partial}{\partial \mathbf{k}} \right| \Psi_k^{(\alpha)} \right\rangle \quad (1)$$

and interband

$$\mathcal{A}^{\alpha\alpha_1}(\mathbf{k}) = \left\langle \Psi_k^{(\alpha)} \left| i \frac{\partial}{\partial \mathbf{k}} \right| \Psi_k^{(\alpha_1)} \right\rangle \quad (2)$$

Berry connections. Here $\alpha_1 \neq \alpha$. While the intraband Berry connection, $\mathcal{A}^{\alpha\alpha}$, determines the accumulation of the phase of an electron that is transferred through the band α , the interband Berry connection $\mathcal{A}^{\alpha\alpha_1}$ is proportional to the interband dipole matrix element.

Solids in a field of an optical pulse

First, we describe the general theory of the interaction of ultrastrong and ultrashort optical pulses with topological materials. The amplitude of the electric field in such pulses is around $\text{IV}/\text{\AA}$ and the duration of the pulses is ~ 10 fs. The pulse should be short enough so it strongly affects the electron dynamics but does not damage the solid itself. At the same time for such a short pulse, less than 10 fs, the scattering processes do not affect the electron dynamics and the dynamics can be considered as a coherent one. The coherent electron dynamics in the time-dependent field of the optical pulse is described by the time dependent Schrödinger equation (TDSE)

$$i\hbar \frac{d\Psi}{dt} = H(t)\Psi, \quad H(t) = H_0 - e\mathbf{F}(t) \cdot \mathbf{r}, \quad (3)$$

where $H(t)$ is the Hamiltonian of an electron system, which consists of the field-free Hamiltonian, H_0 , and the part, which describes the interaction of electrons with the field of the pulse, $-e\mathbf{F}(t)\mathbf{r}$. Here, $\mathbf{F}(t)$ is the pulse's electric field, e is the electron charge, and we used the length gauge to describe the interaction of the optical pulse with the solid.

In solids, which have a multi-band structure, the electric field of the pulse generates two types of electron dynamics. The first one is the intraband adiabatic dynamics, which is determined by the Bloch acceleration theorem (Bloch, 1929). This theorem determines the time evolution of the wave vector, $\mathbf{k}(t)$, in the time-dependent electric field, $\mathbf{F}(t)$

$$\mathbf{k}(\mathbf{q}, t) = \mathbf{q} + \frac{e}{\hbar} \int_{-\infty}^t \mathbf{F}(t') dt', \quad (4)$$

where $\mathbf{k}$ is the electron crystal wave vector and $\mathbf{q}$ is its initial value, i.e., before the pulse, $\mathbf{q} = \mathbf{k}(\mathbf{q}, -\infty)$. The intraband electron dynamics is adiabatic, i.e., after the pulse, an electron returns to its initial state with initial wave vector, $\mathbf{q}$, while the electron wave function can get an extra phase, the Berry phase.

The adiabatic solutions of the Schrödinger equation (3), which are the solutions within a single band α , i.e., without an interband coupling, are the well-known Houston functions (Houston, 1940)

$$\Phi_{\alpha\mathbf{q}}^{(H)}(\mathbf{r}, t) = \Psi_{\mathbf{k}(\mathbf{q}, t)}^{(\alpha)}(\mathbf{r}) \exp \left(i\phi_{\alpha}^{(D)}(\mathbf{q}, t) + i\phi_{\alpha}^{(B)}(\mathbf{q}, t) \right), \quad (5)$$

where $\alpha = 1, \dots, N$ is the band index and N is the number of bands. Here the dynamic phase, $\phi_{\alpha}^{(D)}$, and the geometric phase, $\phi_{\alpha}^{(B)}$, are defined as

$$\phi_{\alpha}^{(D)}(\mathbf{q}, t) = \frac{-1}{\hbar} \int_{-\infty}^t dt' (E_{\alpha}[\mathbf{k}(\mathbf{q}, t')]), \quad (6)$$

$$\phi_{\alpha}^{(B)}(\mathbf{q}, t) = \frac{e}{\hbar} \int_{-\infty}^t dt' \mathbf{F}(t') \cdot \mathcal{A}^{\alpha\alpha}[\mathbf{k}(\mathbf{q}, t')]. \quad (7)$$

The geometric phase or the topological phase is determined by the nontrivial topological properties of the solid. After the pulse, this phase can result in an extra nontrivial phase to the wave function, $\phi_{\alpha}^{(B)}(\mathbf{q}, t = \infty)$, that can be expressed as

$$\begin{aligned} \phi_{\alpha}^{(B)}(\mathbf{q}, t = \infty) &= \frac{e}{\hbar} \int_{-\infty}^{\infty} dt' \mathbf{F}(t') \cdot \mathcal{A}^{\alpha\alpha}[\mathbf{k}(\mathbf{q}, t')] \\ &= \oint_{C_{\mathbf{q}}} d\mathbf{k} \cdot \mathcal{A}^{\alpha\alpha}(\mathbf{k}), \end{aligned} \quad (8)$$

where the Bloch acceleration theorem has been used and the last integral is calculated over a closed electron trajectory in the reciprocal space. For such a trajectory, $\mathbf{q}$ is the initial wave vector and the trajectory is determined by the field of the pulse. The nontrivial topological phase can be accumulated only for a circularly (elliptically) polarized pulse, for which an electron trajectory is of a circular (elliptical) shape.

The interband electron dynamics results in redistribution of electrons between the bands. This dynamics is determined by solutions of TDSE (3). The solutions can be parameterized by the initial wave vector $\mathbf{q}$ and can be expanded in the basis of Houston functions $\Phi_{\alpha\mathbf{q}}^{(H)}(\mathbf{r}, t)$ as

$$\Psi_{\mathbf{q}}(\mathbf{r}, t) = \sum_{\alpha=1}^N \beta_{\alpha\mathbf{q}}(t) \Phi_{\alpha\mathbf{q}}^{(H)}(\mathbf{r}, t), \quad (9)$$

where $\beta_{\alpha\mathbf{q}}(t)$ are the expansion coefficients, which satisfy the following system of equations

$$i\hbar \frac{\partial \beta_{\alpha\mathbf{q}}(t)}{\partial t} = - \sum_{\alpha_1 \neq \alpha} e\mathbf{F}(t) \cdot \mathcal{A}^{\alpha\alpha_1}(\mathbf{q}, t) e^{i(\phi_{\alpha\alpha_1}^{(D)}(\mathbf{q}, t) + \phi_{\alpha\alpha_1}^{(B)}(\mathbf{q}, t))} \beta_{\alpha_1\mathbf{q}}(t) \quad (10)$$

Here

$$\phi_{\alpha\alpha_1}^{(D)}(\mathbf{q}, t) = \phi_{\alpha_1}^{(D)}(\mathbf{q}, t) - \phi_{\alpha}^{(D)}(\mathbf{q}, t) \quad (11)$$

$$\phi_{\alpha\alpha_1}^{(B)}(\mathbf{q}, t) = \phi_{\alpha_1}^{(B)}(\mathbf{q}, t) - \phi_{\alpha}^{(B)}(\mathbf{q}, t) \quad (12)$$

$$\mathcal{A}^{\alpha\alpha_1}(\mathbf{q}) = \left\langle \Psi_{\mathbf{q}}^{(\alpha)} \left| i \frac{\partial}{\partial \mathbf{q}} \right| \Psi_{\mathbf{q}}^{(\alpha_1)} \right\rangle, \quad (13)$$

and $\mathcal{A}^{\alpha\alpha_1}(\mathbf{q})$ is the interband (non-Abelian) Berry connection (Wilczek and Zee, 1984; Xiao et al., 2010; Yang and Liu, 2014), which is proportional to the interband dipole matrix elements, $\phi_{\alpha\alpha_1}^{(D)}(\mathbf{q}, t)$ is the transition dynamic phase, and $\phi_{\alpha\alpha_1}^{(B)}(\mathbf{q}, t)$ is the transition Berry phase.

The interband transitions between the bands α and α_1 are determined by the effective dipole matrix element

$$\begin{aligned} \mathbf{D}_{\alpha\alpha_1}^{(eff)} &= \mathcal{A}^{\alpha\alpha_1}(\mathbf{q}, t) e^{i(\phi_{\alpha\alpha_1}^{(D)}(\mathbf{q}, t) + \phi_{\alpha\alpha_1}^{(B)}(\mathbf{q}, t))} \\ &= |\mathcal{A}^{\alpha\alpha_1}(\mathbf{q}, t)| e^{i(\phi_{\alpha\alpha_1}^{(D)}(\mathbf{q}, t) + \phi_{\alpha\alpha_1}^{(B)}(\mathbf{q}, t) + \phi_{\alpha\alpha_1}^{(A)}(\mathbf{q}, t))}, \end{aligned} \quad (14)$$

where $\phi_{\alpha\alpha_1}^{(A)}$ is the phase of the interband Berry connection.

The solution of the system (10) determines the different characteristics of the interaction of optical pulses with solids. Namely, the pulse-induced population of the conduction band both during the pulse and after the pulse, the electric current generated during the pulse and the corresponding transferred charge through the system, absorbance of the optical pulse, and generation of high optical harmonics during the pulse. The residual conduction band population, i.e., the conduction band population after the pulse, also characterizes the level of irreversibility of the electron dynamics during the pulse.

The electron dynamics in the field of the pulse is completely determined by the properties of the effective dipole matrix element, $\mathbf{D}_{\alpha\alpha_1}^{(eff)}$ [see Eq. 14]. In the graphene-like topological materials, the topology affects both the amplitude of $\mathbf{D}_{\alpha\alpha_1}^{(eff)}$ and its phase, i.e., the topological phase, resulting in some nontrivial features in the ultrafast electron dynamics. Below we discuss some specific properties of such dynamics in graphene-like materials.

Fig. 1 (A) Honeycomb crystal structure of graphene-like materials. It consists of two sublattices, A and B. For a system with inversion symmetry, like pristine graphene, two sublattices are equivalent and the system has zero bandgap at two valleys K and K' (Dirac points) in the reciprocal space, which are shown in panel (B). For a system with broken inversion symmetry, just as the TMDC monolayer, the sublattices are not equivalent and the system has a finite bandgap. Panel (B) shows the first Brillouin zone of graphene-like materials. Points K and K' correspond to two valleys of the low-energy spectrum. The blue arrows illustrate the x and y components of the applied field due to an external optical pulse.

Topological properties of graphene-like materials

Graphene-like materials have hexagonal lattice structure, which is shown schematically in Fig. 1A. The lattice has two sublattices, “A” and “B”. Pristine graphene, which is a monolayer of carbon atoms, has inversion symmetry and two sublattices are equivalent. The lattice structure is determined by the lattice vectors $\vec{a}_1 = a/2(\sqrt{3}, 1)$ and $\vec{a}_2 = a/2(\sqrt{3}, -1)$. Here a is the lattice constant, which for graphene is 2.46 Å. The first Brillouin zone of graphene-like materials is a hexagon, see Fig. 1B, with the vertices at the $K = (2\pi/a)(1/3, 1/\sqrt{3})$ and $K' = (2\pi/a)(-1/3, 1/\sqrt{3})$ points. These points are called the Dirac points. For graphene, the low energy dispersion near these points are described by the Dirac gapless relativistic equation. The points K and K' are connected by the time-reversal symmetry and are two valleys of graphene-like materials.

The simplest model of graphene, which captures its essential properties, is a nearest-neighbor tight-binding model, which describes coupling between the two sublattices A and B with the coupling constant $\gamma = 3.03$ eV (see Fig. 1). In the reciprocal space the corresponding Hamiltonian H_0 is a 2×2 matrix, which has the following form

$$H_0 = \begin{pmatrix} 0 & \gamma f(\mathbf{k}) \\ \gamma f^*(\mathbf{k}) & 0 \end{pmatrix} \quad (15)$$

where

$$f(\mathbf{k}) = \exp\left(i\frac{ak_x}{\sqrt{3}}\right) + 2\exp\left(-i\frac{ak_x}{2\sqrt{3}}\right)\cos\left(\frac{ak_x}{2}\right). \quad (16)$$

The energy spectrum of the Hamiltonian H_0 consists of the conduction and valence bands with the corresponding energy dispersions $E_c(\mathbf{k}) = -\gamma |f(\mathbf{k})|$ and $E_v(\mathbf{k}) = \gamma |f(\mathbf{k})|$ with the wave functions of the form

$$\Psi_{\mathbf{k}}^{(c)} = \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{\sqrt{2}} \begin{pmatrix} 1 \\ e^{-i\phi_{\mathbf{k}}} \end{pmatrix} \quad (17)$$

and

$$\Psi_{\mathbf{k}}^{(v)} = \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{\sqrt{2}} \begin{pmatrix} -1 \\ e^{-i\phi_{\mathbf{k}}} \end{pmatrix}. \quad (18)$$

Here the subscripts “c” and “v” stand for the conduction band and the valence band, respectively. The parts of the wave functions without $e^{i\mathbf{k}\cdot\mathbf{r}}$ are the Bloch functions, which are used to calculate the intraband and interband Berry connections. The Berry connections are singular or have maximum at the Dirac points, i.e. at the K and K' points. To understand their properties we consider a low energy effective model of graphene, which is described by the Dirac massless Hamiltonian.

The Hamiltonian H_0 describes the pristine graphene, which has an inversion symmetry and the corresponding energy dispersion is gapless. For graphene placed on a substrate or for other graphene-like materials, such as TMDC monolayers, the inversion symmetry is broken and two sublattices A and B becomes inequivalent, which can be described by an extra mass term of the form

$$H_{\Delta} = \begin{pmatrix} \Delta/2 & 0 \\ 0 & -\Delta/2 \end{pmatrix}. \quad (19)$$

The extra term which breaks the inversion symmetry of the system, opens a bandgap Δ at the Dirac points.

To understand the topological properties of two-dimensional (2D) graphene-like materials we first consider the low energy effective model of gapped graphene. This model covers both graphene with broken inversion symmetry due to, for example, a

substrate, and also other graphene-like materials, such as TMDCs, black phosphorus, silicene, germanene, and so on. The model is described by the following Hamiltonian

$$H_D = \begin{pmatrix} \Delta/2 & \hbar\tau v_F(k_x - ik_y) \\ \hbar\tau v_F(k_x + ik_y) & -\Delta/2 \end{pmatrix}, \quad (20)$$

where $v_F \sim 10^6$ m/s is the Fermi velocity and τ is the valley index, which is 1 for the K valley and -1 for the K' valley. The energy spectrum of the low energy Hamiltonian H_D is given by the following expressions

$$E_c(\mathbf{k}) = \sqrt{\left(\frac{\Delta}{2}\right)^2 + \hbar^2 v_F^2 k^2} \quad (21)$$

for the conduction band and

$$E_v(\mathbf{k}) = -\sqrt{\left(\frac{\Delta}{2}\right)^2 + \hbar^2 v_F^2 k^2} \quad (22)$$

for the valence band.

With the known wavefunctions, the Berry connections, both intraband and interband, can be found. The effective dipole matrix element, which determines the coupling between the valence and the conduction bands, depends on the transition Berry phase, $\phi_{vc}^{(B)}(\mathbf{q}, t)$, which is proportional to the difference $\mathcal{A}^{vv} - \mathcal{A}^{cc}$. For the effective model, this difference is

$$\mathcal{A}^{vv} - \mathcal{A}^{cc} = \frac{\tau\Delta}{2E_c(\mathbf{k})} \frac{[\hat{\mathbf{z}} \times \mathbf{k}]}{k^2}. \quad (23)$$

This expression shows that if a graphene-like system is gapless, $\Delta = 0$, i.e., the system has inversion symmetry, then $\mathcal{A}^{vv} - \mathcal{A}^{cc} = 0$ and the effective coupling of the valence and conduction bands does not depend on the intraband Berry connection. Thus, for such systems, even for the topologically nontrivial materials like pristine graphene the topology does affect ultrafast electron dynamics in a sense that it does not bring an extra topological phase into the problem.

For graphene-like systems with broken inversion symmetry, i.e., $\Delta \neq 0$, the difference $\mathcal{A}^{vv} - \mathcal{A}^{cc}$ is nonzero and the intraband Berry connection brings an extra topological phase into the effective coupling, which results, as we will see below, in the effect of topological resonance, when the topological phase cancels the dynamic phase and enhances the interband electron transfer.

Another manifestation of the topology comes from the interband Berry connection, which is proportional to the interband dipole matrix element. For the low energy model, the interband Berry connection takes the following form

$$\mathbf{A}^{cv} = \frac{v_F}{2kE_c(\mathbf{k})} \left\{ \tau[\hat{\mathbf{z}} \times \mathbf{k}] + i \frac{\Delta}{2E_c(\mathbf{k})} \mathbf{k} \right\}. \quad (24)$$

There are two effects of the inter band Berry connection on the electron dynamics. The first one is due to an extra contribution, $\phi_{cv}^{(A)}$, to the topological phase of the effective inter band coupling, and the second effect is related to the amplitude of $\mathcal{A}^{cv}$.

We can see from Eq. (24) that phase $\phi_{cv}^{(A)}$ is zero for the systems with inversion symmetry, i.e., for $\Delta = 0$. Thus for topological systems without the band gap, the total topological phase, which includes both intraband and interband contributions, in the effective interband coupling is zero and does not affect the ultrafast electron dynamics.

We can understand the properties of the amplitude of $\mathcal{A}^{cv}$, i.e., the magnitude of the interband coupling, by considering the case of $\Delta = 0$. Then from Eq. (24) we can find the following expression

$$|\mathcal{A}_x^{cv}| = \frac{|k_y|}{2\hbar(k_x^2 + k_y^2)}, \quad (25)$$

$$|\mathcal{A}_y^{cv}| = \frac{|k_x|}{2\hbar(k_x^2 + k_y^2)} \quad (26)$$

The magnitude of the interband coupling is singular at the $\mathbf{k} = 0$ point. For example, at $k_x = 0$, $|\mathcal{A}_x^{cv}|$ behaves as $1/|k_y|$, which shows that the interband coupling is the strongest at the Dirac points, i.e., the $\mathbf{k} = 0$ points. For $\Delta \neq 0$, the singularity of the interband coupling becomes less pronounced but still the coupling has the maxima at the Dirac points.

The ultrafast electron dynamics in the field of the pulse is therefore characterized by the following properties of the effective interband dipole coupling: (i) The magnitude of the interband coupling has well pronounced maxima at the Dirac points. This property results in the interference effects (Keldar et al., 2015, 2016), which will be discussed below. They are visible as bright spots in the conduction band population distribution in the reciprocal space and can be observed in graphene-like systems with zero or small bandgap, Δ . (ii) The effective interband coupling has a topological phase, which is accumulated during the pulse and compete with the dynamic phase resulting in topological resonance (Oliaei Motlagh et al., 2018, 2019a). The topological resonance produces large valley polarization in graphene-like materials placed in the field of a circularly polarized pulse. Since the topological phase is nonzero only in the systems with broken inversion symmetry, the topological resonance can be observed only if $\Delta \neq 0$.

Ultrafast electron dynamics: Interference effects

For strong optical pulses, an electron is transferred during the pulse through almost the entire Brillouin zone. In this case, to have a realistic description of ultrafast electron dynamics, the tight-binding model should be considered, for which the system of differential equations (10) has to be solved at all points in the first Brillouin zone. The main characteristics of the electron dynamics is the residual conduction band population, i.e., the population after the pulse. To observe the interference effects in the CB population distribution in the reciprocal space, a short linearly polarized pulse can be considered. The simplest profile of such a pulse with just a single oscillation of electric field is given by the following expression

$$F_x = F_0 e^{-u^2} (1 - 2u^2), \quad (27)$$

where $u = t/\tau$, $\tau = 1$ fs, and F_0 is the amplitude of the pulse. The pulse satisfies the condition that the area under the pulse is zero, $\int_{-\infty}^{\infty} F_x(t) dt = 0$.

For such a pulse, an electron twice passes the region near the Dirac point, where the interband coupling is the strongest, resulting in the interference of the two pathways (Kelardeh et al., 2015; Koochaki Kelardeh et al., 2017). The origin of the interfering pathways can be understood from Fig. 2. Here the first path, shown by the red line in the left panel, describes the following process: during the first passage of the Dirac point an electron is transferred from the valence band to the conduction band and during the second passage it remains in the conduction band. The second path is shown by the blue line in the right panel. It describes the following process: during the first passage of the Dirac point the electron remains in the valence band, but during the second passage it is transferred to the conduction band. The dynamic phases accumulated along these paths determine if the interference corresponding to two pathways constructive or destructive.

First, we consider the case of pristine graphene, i.e., $\Delta = 0$, for which the interband coupling has well pronounced maxima at the Dirac points. The residual CB population distribution is shown in Fig. 3 for different field amplitudes. The distribution clearly illustrates the interference patterns with bright and dark spots corresponding to the constructive and destructive interference, respectively. Such interference occurs only for electrons, which, during the pulse, can reach the Dirac points. With increasing pulse amplitude the electrons from the farther regions in the reciprocal space can pass the Dirac points. As a result, with increasing F_0 the interference region becomes larger, which is clearly visible in Fig. 3. For instance, while for $F_0 = 0.4$ V/Å the interference fringes are realized only near the Dirac points, at $F_0 = 2.25$ V/Å, the interference pattern occupies the whole Brillouin zone. Therefore, the number of observable bright spots is proportional to the magnitude of the optical pulse. At the same time the distance between the bright spots depends only on the frequency of the pulse but not on its amplitude.

The origin of the interference effects in the coherent electron dynamics is the highly localized nature of the interband coupling at the Dirac points. Such localization is well pronounced in pristine graphene, which has zero bandgap, $\Delta = 0$. As it was shown in the previous section, for graphene-like materials with broken inversion symmetry, i.e., $\Delta > 0$, with increasing bandgap the interband coupling as a function of the reciprocal vector becomes broadened. As a result the interference pattern in the conduction band population distribution becomes less pronounced and with less contrast (Oliaei Motlagh et al., 2019b). This property is illustrated in Fig. 4 where the numerical data are shown for gapped graphene with different bandgaps.

Fig. 2 Two interfering pathways, which result in the interference effects in coherent electron dynamics in graphene-like materials. Each pathway corresponds to two passages of the Dirac point during intraband electron dynamics. The interband coupling is the strongest near the Dirac point. An electron, which is initially in the valence band, while passing the Dirac point in the reciprocal space, can be transferred to the conduction band or remains in the valence band. Similarly, if an electron is initially in the conduction band then, while passing the Dirac point, it can be transferred to the valence band or remain in the conduction band. Then, the left panel shows the first interfering path, when an electron during the first passage of the Dirac point is transferred to the conduction band and then stays in the conduction band, while the right panel shows the second interfering pathway, when an electron is transferred to the conduction band during the second passage of the Dirac point.

Fig. 3 Conduction band population distribution in the reciprocal space for pristine graphene placed in linearly polarized optical pulse. The pulse is polarized in the x direction. Different panels correspond to different field amplitudes F_0 . The data illustrate the interference effects in the coherent electron dynamics induced by a strong and short optical pulse. With increasing field amplitude the number of visible dark and bright fringes increase, while the distance between the bright spots is determined by the frequency of the pulse but not its amplitude. Reproduced with permission from Kelardeh HK, Apalkov V, and Stockman MI (2015) *Physical Review B* 91(4): 045439, doi: 10.1103/PhysRevB.91.045439.

Fig. 4 Conduction band population distribution for gapped graphene-like material in the field of the linearly polarized optical pulse. The pulse is polarized in the x direction. Different panels correspond to different values of the bandgap, Δ , as marked in the figure. At small bandgaps, the interference pattern has large contrast, while the contrast becomes much less pronounced with increasing bandgap. This is due to the properties of the interband dipole matrix element, which has sharp maxima at the Dirac points only in the systems with small bandgap. Reproduced with permission from Oliaei Motlagh SA, Nematollahi F, Mitra A, Zafar AJ, Apalkov V, and Stockman MI (2019b) *Journal of Physics: Condensed Matter* 32(6): 065305, ISSN 0953-8984 1361-648X, doi:10.1088/1361-648X/ab4fc7.

The interference fringes are formed only if an electron passes the Dirac point at least twice during the field-induced transfer in the reciprocal space. It happens for a linearly polarized pulse as shown in Figs. 3 and 4 and can also occur for a circularly polarized pulse with at least two oscillations (Keldar et al., 2016).

Ultrafast electron dynamics: Topological resonance

The interference effects discussed in the previous section are realized in the systems with relatively small bandgap, Δ , so that the magnitude of the effective interband coupling has sharp maxima at the Dirac points. At the same time, if the bandgap is small, then the topological phase of the effective interband coupling is almost zero. That means the phase is proportional to the bandgap of the graphene-like system. At large bandgap, the phase of the interband coupling is nonzero and in this case another effect in topological materials can be observed (Oliaei Motlagh et al., 2018, 2019a). It is called the topological resonance and is realized when the accumulated topological phase cancels the dynamic phase. The condition of the topological resonance between the two bands α and α_1 can be expressed through the following relation

$$\frac{d}{dt} [\phi_{\alpha\alpha_1}^{(D)}(\mathbf{q}, t) + \phi_{\alpha\alpha_1}^{(B)}(\mathbf{q}, t) + \phi_{\alpha\alpha_1}^{(A)}(\mathbf{q}, t)] = 0 \quad (28)$$

If this condition is satisfied then, assuming that the time variations of the magnitude of the interband coupling and the field itself are small, the mixing of the bands α and α_1 is strong. For example, if the two bands are the valence and conduction bands, then under the condition of the topological resonance there is a strong transfer of electrons from the valence band to the conduction band. The most important property of expression (28) is that the condition of the topological resonance depends on the valley index, τ . This is because the topological phase has opposite signs at the K and K' valleys (see Eqs. (23), (24)). As a result, if the topological resonance is observed in one of the valley then it cannot be realized in another valley. Due to this property, after a specially designed pulse, the residual conduction band populations of the two valleys can be different, resulting in valley polarization. The graphene-like systems, even with the finite bandgap, have time reversal symmetry. In this case to observe the residual, i.e., after the pulse, valley polarization, a circularly polarized pulse, which breaks the time reversal symmetry, should be applied. The valley polarization produced by an ultrashort circular pulse is shown in Fig. 5. It is realized only in gapped graphene

Fig. 5 Conduction band population distribution in the reciprocal space for gapped graphene-like material placed in a single oscillation circularly polarized pulse. The profile of the pulse is shown in the inset. The amplitude of the pulse is 0.5 V/Å. Different panels correspond to different values of the bandgap as marked in the figure. Large valley polarization induced by optical pulse is visible only for systems with large bandgap, while for zero bandgap materials, such as pristine graphene, the valley polarization is exactly zero. The origin of the valley polarization in graphene-like materials is the topological resonance, which occurs only in systems with broken inversion symmetry, i.e., with the finite bandgap. Reproduced with permission from Oliaei Motlagh SA, Nematollahi F, Apalkov V, and Stockman MI (2019a) *Physical Review B* 100(11): 115431, doi: 10.1103/PhysRevB.100.115431.

systems, while no valley polarization is visible in pristine graphene, i.e., at $\Delta = 0$. The origin of the valley polarization after a femtosecond-long pulse is the topological resonance, when the topological phase cancels the dynamic phase. The valley polarization in gapped graphene systems can be also produced by a continuous-wave circularly polarized pulse. In this case the pulse is long and weak and the origin of the valley polarization is an intrinsic chiral property of the interband dipole matrix element, i.e., $\mathcal{A}_x^{cv} \pm i\mathcal{A}_y^{cv} \propto (1 \pm \tau)$. Thus, the left circular polarized pulse excites electrons in the K valley only, while the right circularly polarized pulse excites the K' valley. The topological resonance, which can happen only in a strong and short pulse, can not be realized in a continuous-wave pulse, for which the electron excursion in the reciprocal space is very small and no topological phase can be accumulated during the pulse.

The topological resonance, which is due to compensation of the dynamic phase by the topological phase, is similar to the regular resonance, when the dynamic phase is compensated by the time dependent phase of the field of the pulse, i.e., $\exp(i\omega t)$, where ω is the frequency of the pulse. The fundamental difference between these two resonances is that the regular resonance depends on the frequency of the pulse but not on its amplitude, while the topological resonance depends on the amplitude of the pulse but not on its frequency.

The valley polarization induced by an ultrashort optical pulse is the fundamentally fastest possible induction of the valley polarization in graphene-like systems. The examples of the gapped graphene systems are TMDC monolayers. The minimal tight binding model of TMDC materials consists of three bands, which come from the coupling of the nearest neighbor metal d orbitals (Liu et al., 2013). The TMDC materials also have strong spin-orbit interaction compared to graphene. Since the low energy physics in TMDC monolayers can be described within the effective model of gapped graphene, interaction of TMDC monolayers with femtosecond long circularly polarized pulse also results in finite residual valley polarization (Motlagh et al., 2018).

The valley polarization induced by a circularly polarized pulse in gapped graphene like materials can be probed by a linearly polarized pulse. Such a linearly polarized pulse produces anomalous all optical Hall current (Motlagh and Apalkov, 2021). The Hall current is due a preferable population of one of the valleys.

In 2D graphene-like materials with broken inversion symmetry, topological resonance results in finite residual valley polarization when such materials are placed in circularly polarized optical pulse. Topological resonance can be also observed in 3D topological materials, such Weyls semimetals (Nematollahi et al., 2019). In this case, the topological resonance does not preferably populate a specific Dirac point, but results in asymmetric conduction band population distribution around the Dirac points.

Conclusion

Ultrastrong optical pulses can induce not only strong interband mixing in solids, resulting, for example, in ultrashort metallization of a dielectric, but also adiabatically mix the states within a single band, which can be understood as an electron transfer within a band. In topological materials, during such transfer an electron can accumulate a topological phase. Such a phase can modify the interband electron transfer resulting in topologically related effects in ultrafast electron dynamics. The examples of solids with nontrivial topological properties are graphene-like materials. Although globally these materials do not have any net topological charge, locally, they have nontrivial topological properties, which are characterized in terms of the Berry connection or the Berry curvature. The graphene-like materials also have two valleys, which are related by the time reversal symmetry and have opposite topological charges.

The topologically-induced effects that can be observed in graphene-like materials are determined by another symmetry, which can be present in honeycomb crystal systems. This is the inversion symmetry. If the graphene-like system has the inversion symmetry, like in pristine graphene, then the system is gapless, but if the inversion symmetry is broken then the system is semiconductor with a finite bandgap, like TMDC monolayers.

In graphene-like materials with inversion symmetry or weakly broken inversion symmetry, i.e., with small bandgap, the interference effects in the interband electron dynamics can be observed. These effects are visible as bright and dark spots in the conduction band population distribution in the reciprocal space. Experimentally, such highly nonuniform distribution can be measured by angle-resolved photoemission spectroscopy technique. With increasing the bandgap, the interference effects become strongly suppressed. In this case, the effect of topological resonance can be observed if graphene-like materials are placed in the field of ultrashort and ultrastrong optical pulses. This effect is purely topological and is due to cancellation of the dynamic phase by the topological phase, where the topological phase is accumulated during an electron transfer in the reciprocal space. The topological resonance results in ultrafast valley polarization in gapped graphene-like materials placed in the field of a circularly polarized pulse.

Abstract

Electromagnetically induced transparency (EIT) is an important effect which renders an otherwise optically opaque medium transparent to light over a narrow spectral region. The effect has been observed in atomic gases, molecules and solids when subject to external laser irradiation. The article focuses on the necessary background tools to understand the underlying physics while overviewing some of the most relevant prospects.

Key points

- Electromagnetically induced transparency (EIT) describes a phenomenon by which an opaque optical medium becomes transparent due to quantum interference effects.
- EIT has been observed in atomic, molecular and solids media.
- EIT has been widely employed to control light wave propagation, including control of the refractive index and enhancement of optical nonlinearities.
- EIT is crucial for the development of next generation optical memories, quantum communications and modern quantum sensing as well as for the control of single-photons devices.

Introduction

Electromagnetically induced transparency effects are rather subtle (Harris, 1997; Marangos, 1998) and rely on states quantum coherence and interference. Three-level atomic and molecular systems coupled to two laser fields are archetype setups where the effect occurs as a result of the cancellation of absorption at a resonance transition frequency. The transparency resulting from such an absorption quenching is deliberately induced by one of the two laser fields upon modifying the medium optical response to the other field. The large degrees of transparency observed in a medium where strong absorption would normally be expected has then been termed *electromagnetically induced transparency (EIT)*.

Such a phenomenon has been exploited to either control or eliminate the hampering effects that certain materials have on a propagating light beam and, in particular, to control the group velocity of light pulses. Most celebrated is the achievement of two extreme regimes for ultrafast and ultraslow light propagation where a light pulse may travel faster than c , the speed of light in vacuum, or may rather slow down at the a bike's pace of a few meters per second. It has also been used to bring light to a full stop inside a medium hence laying the ground for photon storage techniques to be exploited in modern quantum memories. From the outset, EIT has also stimulated a considerable amount of work on fundamental issues: nonlinear optics at low-light levels, photon entanglement and entanglement of atomic ensembles, quantum information processing and storage as well as enhanced acousto-optical effects, just to mention a few. Some of these have been observed over the past decades or so while others continue to spur interest in the quest for all-optical lightwave control for the next generation integrated photonic devices.

[☆]Change History: October 2022. M Artoni has updated the introduction section, added 22 recent references, Figure 7-8, and refined the diction of all figures captions. The Section "EIT Analogue" was added and the section "Conclusions and prospects" has been thoroughly rewritten and extended to include for recent applications as well as new directions in the field.

We will start with a preliminary brief discussion on coherent population trapping, a closely related effect whose observation first raised interest in induced transparency phenomena. The core of the article will then provide the necessary understanding of the physics underlying the phenomenon of electromagnetically induced transparency while a brief outline of some topical challenges and opportunities will be given in the concluding sections.

Coherence and population trapping

Cancellation of absorption due to the coherence between a pair of atomic states and subsequent trapping of the population is perhaps one of the earliest examples of transparency induced in an otherwise absorbing medium. Specifically, the coherent superposition of two atomic states leads under certain conditions to trapping of the population and hence to transparency. This typically occurs in three level atomic systems, or at least systems that can be adequately reduced to a three levels configuration when interaction with two electromagnetic fields is considered. A basic configuration leading to effects of coherent population trapping (CPT) is reported in Fig. 1.

The phenomenon has been first observed in Gozzini's group in Pisa (Alzetta et al., 1976) and later in Stroud's group in Rochester (Whitley and Stroud, 1976). The Pisa group performed experiments that established coherence between the Zeeman split lower levels of sodium atoms using a multimode laser. They employed a spatially varying magnetic field and observed a series of spatially separated dark lines, originally called *dark resonances*, corresponding to the locations where the Zeeman splitting matched the frequency difference between modes of the coupling laser. The other experiment involved instead the hyperfine lower levels of atomic sodium and similar findings were observed. These early observations were explained using the notion of coherent population trapping in a dark-eigenstate of a three-level lambda medium (Arimondo and Orriols, 1976; Gray et al., 1978).

The usual atomic dipole selection rules normally require that two pairs of levels are dipole coupled whilst the transition between the third pair is dipole forbidden. The basic scheme in Fig. 1 comprises the states $|1\rangle$, $|2\rangle$ and $|3\rangle$ coupled by two near-resonance laser fields whose strengths are defined in terms of the Rabi frequencies $\Omega_1 = \mu_{12}\mathcal{E}_1/\hbar$ and $\Omega_2 = \mu_{23}\mathcal{E}_2/\hbar$, respectively. Defining the frequency of transitions between states as $\omega_{21} = (E_2 - E_1)/\hbar$, $\omega_{23} = (E_2 - E_3)/\hbar$ and $\omega_{31} = (E_3 - E_1)/\hbar$ one can further introduce the *one-photon* frequency detuning $\delta_{21} = \omega_{21} - \omega_1$ and $\delta_{23} = \omega_{23} - \omega_2$ as well as the *two-photon* (Raman) detuning $\delta \equiv \delta_{21} - \delta_{23} = (\omega_{21} - \omega_{23}) - (\omega_1 - \omega_2)$.

In a simple treatment the bare atom Hamiltonian $H_0 = \sum_{i=1,2,3} \hbar\omega_i |i\rangle \langle i|$ should be modified to include the interactions due to the two atom-field couplings to obtain in the dipole approximation a total Hamiltonian H of the form (Loudon, 2000).

$$H = H_0 + H_I \equiv H_0 - \frac{\hbar\Omega_1}{2} |2\rangle \langle 1| - \frac{\hbar\Omega_2}{2} |2\rangle \langle 3| + h.c. \quad (1)$$

In general, the eigenstates of H turns out to be linear superpositions of the bare atomic states $|1\rangle$, $|2\rangle$ and $|3\rangle$. At exact resonance ($\delta_{21} = \delta_{23} = 0$) two of the eigenstates of H turn out to be symmetric and antisymmetric *coherent superpositions* of the two lower states of the bare-atom basis (Scully and Zubairy, 1997) namely,

$$\begin{aligned} |C\rangle &= \frac{\Omega_1}{\Omega} |1\rangle + \frac{\Omega_2}{\Omega} |3\rangle \\ |NC\rangle &= \frac{\Omega_2}{\Omega} |1\rangle - \frac{\Omega_1}{\Omega} |3\rangle \end{aligned} \quad (2)$$

where $\Omega = (\Omega_1^2 + \Omega_2^2)^{1/2}$. Note that no component of the bare state $|2\rangle$ appears in these superpositions and that state $|C\rangle$ is coupled to the upper state $|2\rangle$ via the electric-dipole interaction whilst the state $|NC\rangle$ is not. This can easily be seen by evaluating the (dipole) transition matrix element $\langle 2| H_I |NC\rangle$. The two probability amplitudes that are summed to give the whole transition amplitude between $|NC\rangle$ and the atom's upper state $|2\rangle$ have in fact equal and opposite magnitudes. In the present lambda configuration, coherent trapping occurs as due to the destructive quantum interference between the probability amplitudes associated with two

Fig. 1 Lambda (Λ) scheme leading to coherent population trapping (CPT). The applied fields of amplitude $\mathcal{E}_1$ and $\mathcal{E}_2$ with frequencies ω_1 and ω_2 need not be in single-photon resonance, but the two-photon resonance condition ($\delta_{21} \simeq \delta_{23}$) should be met and the field strengths should be of comparable magnitude ($\Omega_1 \approx \Omega_2$). The states $|1\rangle$ and $|3\rangle$ are typically Zeeman or hyperfine sub-levels of the ground state and are initially populated.

(dipole) transitions. Conversely, the transition amplitude $\langle 2 | H_I | C \rangle$ does not cancel to zero and $|C\rangle$ remains coupled to the upper state $|2\rangle$.

When the steady-state regime has been reached, the state $|NC\rangle$ will acquire all the atom's population under the (combined) effects of optical pumping from $|C\rangle$ to $|2\rangle$ and spontaneous emission from $|2\rangle$ to $|NC\rangle$. At last, no absorption process will depopulate the state $|NC\rangle$ where all population will remain *trapped*. The non-coupled state $|NC\rangle$ is often referred to as *dark* state whilst the other state $|C\rangle$, which remains coupled to the fields, is instead referred to as *bright* state.

Electromagnetic induced transparency

A highly opaque medium may be rendered almost transparent also through electromagnetic induced transparency (EIT). Even in this case, as for coherent population trapping, cancellation of absorption relies on a process involving laser-induced coherence and quantum interference between the atomic coherences excited by the electromagnetic fields.

Formally coherences are identified with the off-diagonal elements of the density matrix ρ . Off-diagonal elements of the density matrix play a critical role in the evolution of an atom coupled to electromagnetic fields (Loudon, 2000) and many EIT effects in three-level systems have been investigated in terms of the density matrix (Marangos, 1998; Scully and Zubairy, 1997). Besides, this approach naturally lends itself to the inclusion of dampings that cause the decay of populations and coherences such as, e.g. radiative decay and collisions.

Characteristic configurations for which electromagnetically induced transparency takes place in three-level atoms interacting with two near-resonance electromagnetic fields are shown in Fig. 2. The usual atomic dipole selection rules normally require that $|g\rangle \rightarrow |e\rangle$ and $|e\rangle \rightarrow |m\rangle$ transitions be dipole allowed *but* not the $|g\rangle \rightarrow |m\rangle$ transition. Often $|m\rangle$ is a metastable state. In the Λ or ladder scheme, $|g\rangle$ is normally the ground state of the atom and is where the largest part of the population initially resides while states $|e\rangle$ and $|m\rangle$, which remain essentially unpopulated throughout the process, need not be ground state(s).

To understand how EIT works to reduce absorption when two laser fields interact with a three-level atom we here examine, for definiteness, the Λ configuration in Fig. 2. The states $|g\rangle$ and $|e\rangle$ are coupled by a *probe* field of amplitude $\mathcal{E}_p$ and frequency ω_p while the excited state $|e\rangle$ is coupled to $|m\rangle$ by a *coupling* field of amplitude $\mathcal{E}_c$ and frequency ω_c . The Rabi frequencies of these two fields, proportional to their intensities, are respectively Ω_p and Ω_c . The one-photon detunings δ_p and δ_c as well as the two-photon (Raman) detuning δ are here defined as in the previous section. The off-diagonal decay rates for the coherences ρ_{eg} , ρ_{em} and ρ_{gm} are denoted by γ_1 , γ_2 and γ_3 , respectively. The explicit form of the total hamiltonian H is in this case,

$$H = H_0 + H_1 + H_2 = \sum_{i=g,m,e} \hbar\omega_i |i\rangle \langle i| + H_1 + H_2 \quad (3)$$

Fig. 2 Basic EIT level configurations, with a ladder (or cascade) scheme (upper) and a Λ scheme (lower). State $|m\rangle$ in the Λ scheme need not be a ground state. As for coherent population trapping (CPT) the two-photon (Raman) resonance condition should be met ($\delta_p \simeq \delta_c$), yet the strength of one of the two applied fields could be appreciably larger than the that of the other ($\Omega_p \ll \Omega_c$).

where the atom-field coupling terms are

$$H_1 = -\frac{\mu_{eg} \mathcal{E}_p}{2} e^{-i\omega_p t} |e\rangle \langle g| + h.c.$$

$$H_2 = -\frac{\hbar\Omega_c}{2} e^{-i\omega_c t} |e\rangle \langle m| + h.c.$$

From the Liouville equation for the density matrix ρ one obtains a set of coupled equations connecting the density matrix elements and their temporal derivatives. These equations are usually solved by numerical methods. If a steady-state limit is sought for, however, all time derivatives in the density matrix elements vanish. Under the additional assumption that the coupling field is much stronger than the probe, the former is the only field that must be retained to all orders. Within these two limits one arrives at a simplified form of the coupled density matrix equations and an exact solution can be attained. If initially the atoms are in the ground state $|g\rangle$, i.e.,

$$\rho_{gg}(0) \simeq 1, \rho_{ee}(0) \simeq 0, \rho_{mm}(0) \simeq 0, \rho_{em}(0) \simeq 0, \quad (4)$$

the simplified set of coupled equations for a resonant coupling beam ($\delta_c = 0$) reads as,

$$\dot{\tilde{\rho}}_{eg}(t) = -(\gamma_1 + i\delta_p)\tilde{\rho}_{eg}(t) + \frac{i\mu_{eg} \mathcal{E}_p}{2\hbar} + \frac{i\Omega_c}{2}\tilde{\rho}_{mg}(t)$$

$$\dot{\tilde{\rho}}_{mg}(t) = -(\gamma_3 + i\delta_p)\tilde{\rho}_{mg}(t) + \frac{i\Omega_c}{2}\tilde{\rho}_{eg}(t), \quad (5)$$

where $\delta_p = \omega_{eg} - \omega_p$ denotes the probe field detuning while the new variables $\tilde{\rho}_{eg} = \rho_{eg} e^{i\omega_p t}$ and $\tilde{\rho}_{mg} = \rho_{mg} e^{i(\omega_p + \omega_{me})t}$ have been introduced. In the steady-state limit one has from Eq. (5),

$$\tilde{\rho}_{eg} = \frac{\mu_{eg} \mathcal{E}_p (\delta_p - i\gamma_3)}{(\delta_p - i\gamma_3)(\delta_p - i\gamma_1) - \Omega_c^2/4}. \quad (6)$$

The steady-state coherence (6) is directly proportional to the probe susceptibility χ_p (Loudon, 2000; Scully and Zubairy, 1997) and hence the density matrix off-diagonal element ρ_{eg} describes the medium optical response to the incident probe ω_p and, in particular, its absorption or transparency properties.

The expression for ρ_{eg} contains a number of terms in the various parameters that will lead to cancellation of its value, both real and imaginary parts, when two-photon resonance takes place. In this case, in fact, the real part of (6) is always zero while for appropriately strong coupling beams, or when $\Omega_c^2 \gtrsim \gamma_1\gamma_3$, the imaginary part of (6) is seen to become several orders of magnitude smaller than the value it acquires when the coupling beam is absent, making the medium essentially transparent. It is likewise seen that the lorentzian-like absorption dip obtained by expanding (6) around resonance exhibits a width given approximately by Ω_c^2/γ_1 . Because there exists an upper bound to the coupling beam Rabi frequency Ω_c for EIT to take place, namely $\Omega_c \lesssim \gamma_1$, it then follows that quenching of absorption only takes place over a small bundle of probe frequencies which is appreciably narrower than the natural linewidth γ_1 . Thus under the two-photon resonance condition and in the presence of a coupling whose Rabi frequency Ω_c 's such that (Scully and Zubairy, 1997; Marangos, 1998; Harris, 1997),

$$\sqrt{\gamma_1\gamma_3} \lesssim \Omega_c \lesssim \gamma_1 \quad (7)$$

a probe field can propagate without being absorbed within a small *sub-natural* transparency frequency window, even though it would be strongly absorbed in the absence of the coupling beam.

Within a density matrix formulation the interference that leads to induced transparency manifests itself in the vanishing of the imaginary part of the coherence $\tilde{\rho}_{eg}$.

The real and imaginary parts of the susceptibility exhibited by a probe of frequency ω_p are obtained from the macroscopic polarization $\mathcal{P}(\omega_p) = \epsilon_0 \chi(\omega_p) \mathcal{E}_p$ which can be related, in fact, to the microscopic coherence $\rho_{eg}(\omega_p)$ at ω_p via the expression $\mathcal{P}(\omega_p) = (N/V) \mu_{eg} \rho_{eg}(\omega_p)$ (Loudon, 2000). Here N/V is the atoms density in the medium while μ_{eg} is the dipole matrix element associated with the atomic transition. This relation holds for a medium sufficiently dilute that dipole-dipole coupling between atoms can be ignored. Besides, for the relatively large fields used in most EIT experiments a semiclassical treatment where the fields are treated classically, i.e. in terms of Maxwell's equations and susceptibilities, and the coherences are treated quantum mechanically with spontaneous decay added as a phenomenological damping proves adequate. Only when atoms are coupled to cavities modes or when the statistical properties of light (Artoni and Loudon, 1998) are important a fully quantum approach is indeed required. In the *semi-classical* limit the complex probe susceptibility for a resonant coupling beam ($\delta_c = 0$) can be written as (Artoni et al., 2001a, 2001b)

$$\chi_p = 3\pi\mathcal{N}_p \frac{\Gamma_1(\delta_p - i\gamma_3)}{(\delta_p - i\gamma_3)(\delta_p - i\gamma_1) - \Omega_c^2/4}, \quad (8)$$

where $\mathcal{N}_p$ is the scaled sample average density $N\lambda_p^3/V$ and $\lambda_p = \lambda_p/2\pi$ is the resonant probe reduced wavelength. The expression (8) depends upon parameters, namely detunings and laser intensities, that can all be directly controlled within an experiment.

Fig. 3 Real (upper) and imaginary (lower) part of the probe refractive index n_p as a function of the probe detuning in the absence (dashed) and in the presence (solid) of a resonant coupling beam. The detuning δ_p is in units of γ_1 and the Rabi frequency is $\Omega_c = 0.8 \times \gamma_1$. Due to destructive interference the imaginary part κ_p , associated with medium absorption, vanishes at exact resonance when the coupling field is on. The real part η_p , which determines the medium dispersion, is likewise modified in the presence of the coupling field and acquires a rather steep slope around resonance.

The optical response of a medium is described by its index of refraction that is proportional, in turn, to the susceptibility and hence the optical response of an EIT-medium will in general depend on the (external) coupling beam. The real and imaginary parts of the probe refractive index $n_p \equiv \eta_p + i\kappa_p = \sqrt{1 + \chi_p}$ associated with the medium dispersion and absorption, respectively, are plotted in Fig. 3 as a function of the probe detuning δ_p . The absorption vanishes at exact resonance and this is a striking result when compared with the situation in which the coupling field is absent ($\Omega_c = 0$). Most EIT experiments have carried out on ensembles of atoms. In these experiments one measures the transmission of a *weak* probe in the presence of a *strong* coupling field through an otherwise optically opaque medium. The first demonstration was performed by Harris group at Stanford in two atomic systems, namely strontium (Boller et al., 1991) and lead (Field et al., 1991) vapors. In both experiments narrow-band pulsed laser radiation was used.

In the Sr experiment, the first to be reported and whose results are here shown in Fig. 4, the atoms are pumped into the $4d5d \ ^1D_2$ autoionizing state starting from the $5s5p \ ^1D_2$ state via a pulsed probe laser (337.1 nm) spanning the transition that was to be rendered transparent. A coupling laser (570.3 nm) was instead applied between this autoionizing state and the metastable bound state $4d5p \ ^1D_2$. In the absence of the coupling beam, the probe field excited the system to the state $|2\rangle$ exhibiting strong absorption which made the Sr vapor completely opaque. Transmission, measured as the ratio of the transmitted to the incident intensity, was estimated to be e^{-20} at resonance. When the coupling laser was applied, instead, the resonant transmission increased dramatically to be nearly 40%.

In the Pb experiment, on the other hand, transparency was demonstrated using bound states of a *collisionally* broadened medium. Here a ladder configuration was adopted where probe and coupling beams coupled the $6s^26p7s \ ^3P_1$ excited state respectively to the $6s^26p^2 \ ^3P_0$ ground state and the state $6s^26p7p \ ^3D_1$. These two experiments serve to demonstrate the principle of EIT in three levels systems. They also indicate how electromagnetically induced transparency can take place when the excited states are either autoionizing or collisionally broadened.

Fast and slow light

Along with induced transparency there is a concomitant modification of the refractive properties of the medium. These are characterized by a very steep variation of the real part η of the medium complex refractive index n with frequency as shown, e.g., in Fig. 3. Here, for comparison, η is plotted both in the absence and in the presence of the coupling beam that causes the transparency.

Since in an ideal EIT regime atoms are decoupled from the light fields, the atoms susceptibility vanishes at resonance and the complex index n remains close to unity throughout the EIT transparency window. The propagation speed c/n of a monochromatic beam of light is then essentially unchanged from its speed c in vacuum. This means that the propagation velocity of the beam phase

Fig. 4 EIT in Strontium (Sr) vapors (a) Sr energy levels and Λ configuration with coupling and probe beam of wavelength λ_c and λ_p respectively. Transmission vs. probe laser detuning in the absence (b) and in the presence (c) of a coupling beam. Under the conditions of this experiment transmission goes from zero to about 40%. (Reproduced with permission from Harris S (1997) Electromagnetically induced transparency. *Physics Today* 50: 36).

front in the medium, i.e. its *phase velocity*, is basically c . Yet for a light pulse, which contains instead several Fourier components at different frequencies, the small variations in the phase velocity that each component experiences in the medium can add up to make an appreciable effect. Components with slightly different speeds get in fact out of phase with each other, with the net result that the velocity of the pulse envelope, i.e. its *group velocity*, is different from c (Artori and Loudon, 1997).

Consider, for instance, the superposition of two monochromatic plane waves of the form $\cos[(\omega_o \pm \delta\omega)t - (k_o \pm \delta k)z]$. Addition gives $2\cos[\delta\omega(t - (\delta k/\delta\omega)z)] \cos(\omega_o t - k_o z)$, which is a wave with an amplitude that retains its shape as it propagates with the velocity $\delta\omega/\delta k$. More generally, if we superpose many waves whose frequencies and wave numbers are distributed in a small range about the center values ω_o and k_o , we obtain a wave of the form $A(t - z/v_g) \cos(\omega_o t - k_o z)$. The intensity, averaged over a few optical

periods, is proportional to $A^2(t - z/v_g)$, which describes a light pulse propagating without change of shape at a group velocity v_g defined as $d\omega/dk$.

Using the relation $k = \omega n/c$ with $n = \eta + i\kappa$, one can for very small absorptions ($\kappa \ll 1$) express v_g in terms of the real part η of the refractive index and its derivative $d\eta/d\omega$, so that for a given frequency ω one has (Matsko et al., 2001; Milonni, 2002),

$$v_g(\omega) \equiv \frac{d\omega}{dk(\omega)} = \frac{c}{\eta(\omega) + \omega \frac{d\eta(\omega)}{d\omega}}. \quad (9)$$

In the presence of electromagnetically induced transparency $d\eta(\omega)/d\omega$ is large and positive around resonance as one can see from Fig. 3 and according to (9) very small group velocities can be attained. By substituting the expression (8) into (9) one has indeed at the resonance frequency ω_o ,

$$\frac{v_g^o}{c} \simeq \frac{\Omega_c^2}{6\pi N_p \gamma_1 \omega_o}. \quad (10)$$

Note that v_g^o depends on the control field intensity, proportional to Ω_c^2 , and on the atomic density N/V . Decreasing of the control beam power or increasing of the atomic density can make v_g^o orders of magnitude smaller than the speed of light c in vacuum.

Evidence for ultraslow light is typically provided by measuring the time delay between a pulse propagating in a medium of given length L and a twin pulse that has instead propagated in vacuum. The leading edge of a pulse that enters the medium is in fact rapidly decelerated while its tail outside the medium still propagates at the speed c . As a result, upon entering the medium, the spatial extent of the pulse is compressed (by the ratio c/v_g) and its energy decreased as photons are being expended to establish the coherence between the states $|g\rangle$ and $|m\rangle$, or, in other words, to change atomic state, with any excess energy carried away by the control field. As the pulse exits the medium its spatial extent increases again and the atoms return to their original ground state. The pulse as a whole, however, has experienced a peak-shift Δx given approximately by

$$\Delta x \simeq L \left(1 - \frac{c}{v_g^o} \right) \quad (11)$$

with a concomitant pulse delay τ given by $\Delta x/c$.

The possibility of manipulating the group velocity in EIT media was first pointed out by Harris (1997). The subject, however, was truly brought to focus by a remarkable experiment of Hau et al. (1999) in which an ultracold gas of Na atoms was used to reduce the speed of light pulses at a minimum of 17 m/s! The large and negative pulse delay τ measured in this experiment is reported in Fig. 4 for different experimental conditions. Although the first demonstration of ultraslow light used ultracold gases, shortly thereafter two groups reported ultraslow light propagation in hot Rb gases (Kash et al., 1999; Anon, 1999). This work was a milestone on the way to making ultraslow light “on the cheap”, i.e., without expensive atomic traps (Fig. 5).

Fig. 5 Pulse delay. The front pulse (open circles) is a reference pulse that has propagated in vacuum. The other pulse (filled circles) is delayed by 7.05 μs in a 229- μm -long atom cloud. The corresponding light speed is 32.5 m/s. The curves represent gaussian fits to the measured pulses. (Reproduced with permission from Hau LV et al. (1999) Light speed reduction to 17 metres per second in an ultracold atomic gas. *Nature* 397: 594).

Furthermore, it follows from (9), that group velocities can become infinite or even negative when $d\eta(\omega)/d\omega$ is sufficiently negative, i.e., when the real part of the refractive index decreases with frequency. Because in the visible $\eta(\omega)$ normally increases with frequency the case $d\eta(\omega)/d\omega < 0$, for historical reasons, is called *anomalous dispersion*. Directly from Fig. 3 one sees that in EIT media $\eta(\omega)$ acquires negative slopes just slightly off-resonance. A negative group velocity means that the peak of the pulse emerging from the medium moves faster than the pulse peak that has propagated in vacuum at speed c . This, according to (11), leads to a *positive* peak shift Δx rather than negative ones as obtained in ultraslow light experiments. Such anomalous group velocities can occur without significant pulse distortion. An infinite group velocity, on the other hand, means that the peak of the pulse emerging from the medium occurs at the same time as the peak of the pulse entering the medium as seen again from (11). The pulse, in other words, appears to cross the medium instantaneously. Superluminal peak velocities have been observed, though with substantial pulse attenuation and pulse compression. Such a superluminal behavior does not contradict relativity as the pulse peak velocity is not in general the velocity at which a signal can be transmitted.

Unlike the pioneering experiments that demonstrated anomalous group velocities of single-photons wavepackets carried out nearly a decade ago by Raymond Chiao at Berkeley, the anomalous dispersion regime attained by using electromagnetically induced transparency have been shown to lead to a much larger superluminal effect. Again, these experiments in no way contradict the principle of Einstein causality, i.e., the principle that no *signal* can propagate faster than c because the superluminal peak pulse velocity is not a signal velocity.

Light storage

Recent advances in quantum information science have led to many interesting new concepts such as quantum communications and, in particular, quantum memories (Simon, 2010). The practical implementation of these concepts involves storing, retrieval and transport of quantum states between different nodes of a network. Methods for manipulating photons and their quantum information in EIT atomic media have been extensively investigated (Lukin, 2003; Lvovsky et al., 2009; Ma et al., 2017). Photons are indeed most promising carriers of quantum information: they are fast, robust, and readily available. Atoms, on the other hand, represent reliable and long-lived storage units. These methods essentially consist in trapping single-photon pulses in atomic media by adiabatically reducing their group velocity to zero and subsequently releasing them after a suitable interval of time. Recalling (11) it follows that upon adiabatically ramping down the coupling beam while the probe pulse is inside the atomic sample, its group velocity can actually be brought to zero. The probe pulse, spatially compressed, remains inside the atomic cloud until the coupling beam is switched on again as the storage sequence in Fig. 6 (Liu et al., 2001) clearly shows. This method has been used for coherent storage of a single-photon into a single-atom (Holger et al., 2011), opening the way to implement a single-atom quantum memory, where “write” and “read” operations of states of light “in” and “out” of a single-atom trapped inside an optical cavity can be achieved. This clearly realizes reversible coherent transfer of quantum information carried by light pulses to atoms and vice versa (Lukin, 2003). Although during these early attempts storage times on the order of a second were hard to attain, light pulses can today be coherently stored for up to 1 min and even within solid-state devices (de Riedmatten, 2013).

EIT analogs

Long since its first observation in atomic gases (Harris et al., 1990; Boller et al., 1991), EIT effects have been observed also in solid and molecular compounds. At variance with atoms, solid media exhibit a number of hampering factors (Artori and Birman, 1994)

Fig. 6 Light storage. The reference pulse (open circles) enters the atomic sample while the coupling beam (dashed curve) is switched on. After the coupling beam is adiabatically switched off at around 18 μs the probe pulse is compressed and entirely enclosed within the atomic sample. Revival of the probe pulse takes place after the coupling field is turned off at around 45 μs . During the time interval when the coupling laser is off, coherent information imprinted in the probe pulse, is stored in the atomic medium. (Reproduced with permission from Liu C et al. (2001) Observation of coherent optical information storage in an atomic medium using halted light pulses. *Nature (London)* 409: 490).

as e.g. faster coherence dephasing rates, whereas molecular structures suffer from many decay pathways to lower levels. Much work on EIT effects in a variety of solids and molecules has nevertheless appeared starting with early demonstrations e.g. in quantum wells (Serapiglia et al., 2000) and molecular lithium (Lazoudis et al., 2010).

There exists, in addition, a plethora of EIT-like effects that manifest themselves in altogether different systems such as e.g. in superconductors (Anisimov et al., 2011), metasurfaces (Tassin et al., 2012), nanostructures (Hsu et al., 2014), optomechanical (Dong et al., 2012; Lu et al., 2018) and plasmonics devices (Dyer et al., 2013) as well as in optical resonators (Limonov et al., 2017; Liu et al., 2017) and linearly coupled RLC circuits (Garrido Alzar et al., 2002), just to mention a few. Among them, the latter have been extensively explored in the form of coupled-mode optical platforms where different modes can be simultaneously excited in different micro-cavity resonators (Peng et al., 2014) or even within the same resonator (Xiao et al., 2009; Zhao et al., 2017). Transparency through interference, in fact, can be attained in such otherwise opaque solid micro-cavities. These are ideal platforms for highly tunable all-optical control of transparency owing to the ultrahigh quality factors, on-chip integrability and room temperature operations.

Primarily for the purpose of illustrating an example of EIT-like effects, we briefly review here the basic phenomenology of EIT-like transmission in a single microcavity (Xiao et al., 2009). A tapered fiber with a micrometer size waist is used to evanescently excite two whispering gallery modes (WGM) in a silica coated microtoroid (resonator) stand on a silicon wafer at room temperature (See Fig. 7a, inset). Although it is well known that bringing the two WGM modes (1) and (2) simultaneously on-resonance within a single micro-cavity is difficult, yet one may harness their different thermal responses, viz different modes experience different wavelength shifts when subject the *same* temperature variation. It is this special feature that enables thermal tuning of the spectral distance between the two (far) detuned modes (7a) into resonance as the microcavity surrounding temperature changes. The black solid lines in Fig. 7b through Fig. 7d depict three typical EIT-like transmission spectra corresponding to three different modes detunings that are obtained by gradually increasing the temperature. Notice that mode (2) experiences an appreciable blueshift, at variance with the other mode (1) which shifts very little with temperature. In particular, when the two modes are tuned to overlap (Fig. 7c) the field (1) creates a sharp transparency window within the broad resonant absorption profile of the other field (2); the two fields can then be regarded respectively as “coupling” and “probe” just as in a familiar Λ -configuration of three atomic levels. The transparency window that opens around the control field position may be envisaged as a direct analog of the EIT transparency

Fig. 7 Transmission spectra (solid) from a PDMS-coated silica microtoroid where two largely detuned (a) whispering-gallery modes (1) and (2) are brought to overlap (Reproduced with permission from Xiao YF et al. (2009) Electromagnetically induced, transparency-like effect in a single polydimethylsiloxane-coated silica microtoroid. *Applied Physics Letters* 94: 231115). Red and blue arrows denote respectively the modes resonant wavelengths and the shift direction of mode (2) as the surrounding temperature gradually increases from (b–d) Inset: A scanning electron microscopy (SEM) image of the microtoroid.

Fig. 8 Light coupling into a two-mode microcavity resonator (μR) through a tapered fiber (P_{in}) at near-critical coupling conditions. The interference between the two optical pathways associated with the resonant modes (1) and (2) simultaneously excited in the resonator can lead to *EIT*-like transparency in the transmission spectrum (P_{out}). Here γ_{c1} and γ_{c2} denote the fiber's coupling strength with the two modes (1) and (2), κ represents the direct coupling strength between mode (1) and (2), while γ_1 and γ_2 are the modes intrinsic losses (resonator quality factors).

phenomenon in atomic vapors. Within this context the transparency observed in the transmission spectra at the fiber's exit port (See Fig. 8) can be thought of as due the interference between the two optical pathways simultaneously spun inside the micro-resonator.

The actual transmission line-shapes of Fig. 7b–d are determined by a number of conditions and mainly the coupling strength between the two resonating modes (κ), the coupling between each mode and the fiber (γ_{c1}, γ_{c2}), the modes intrinsic losses as well as the polarizations mismatch (See Fig. 8). The optimization of these conditions remains an important challenge for any realistic implementation of *EIT*-like schemes in solid coupled-mode microcavity platforms.

Conclusion

As of today, we are some 32 years on from the first *EIT* experiments in atomic vapors (Harris et al., 1990; Bollor et al., 1991) and nearly 46 since the earliest demonstrations of coherence effects between pairs of (quantum) atomic states (Alzetta et al., 1976; Whitley and Stroud, 1976), along with their interpretation (Arimondo and Orriols, 1976; Gray et al., 1978) through the introduction of the notion of coherent population trapping (Section “Coherence and population trapping”).

The intense research activity undertaken since then, its various implications and the extensive efforts to harness applications, has made the field to grow, remaining an active subject over so many years and still fostering proposals for novel applications and interesting insights. For such reasons *EIT* has earned quite a significant place in optics, with a profound impact upon far reaching photonics technologies.

The article is meant to illustrate the basic physics behind *EIT*, by which one can eliminate the effect of a medium on a propagating light beam by changing e.g. its absorption or refraction or group velocity. Although basic physics concepts are crucial to understand the phenomenology of *EIT* (Section “Electromagnetic induced transparency”), we have tried to connect also with experiments. Much literature clearly exists, yet we found it instructive to illustrate early pioneering demonstrations (Sections “Fast and slow light” and “Light storage”) as well as more recent developments of *EIT*-like effects (Section “*EIT* analogs”) observed in metamaterials. The latter turn out to have great functionalities in the areas of sensing, slow-light, electromagnetic induced absorption, etc. When turning to the future, on the other hand, predictions are as usual risky, nevertheless we offer here below some thoughts on mainstream applications that are likely to spur new and emerging ones, hopefully stimulating further insights.

First, since the pioneering work on ultraslow light in atomic clouds as e.g. Hau et al. (1999) there has been substantial interest in its potential extension to solids. Slow and even stopped light can now be routinely attained in solid materials easing important steps toward the integration and scalability needed for many potential applications while in turn substantiating early important attempts as, e.g., in semiconductors (Artoni et al., 2000; Serapiglia et al., 2000) and in Ruby crystals either at cryogenic (Turukhin et al., 2002) or at room temperature (Bigelow et al., 2003).

Over the years more sophisticated solid media settings, with similar three-level *EIT* interaction configurations, ranging from hybrid prototypes as e.g. cold-atom photonic crystal-fiber waveguides (Venkataraman et al., 2011; Bajcsy et al., 2011), cold-atom dynamic waveguides (Wu et al., 2009a, 2009b; Wu et al., 2010; Moiseev et al., 2014), miniaturized atomic vapor cells

(Baluktsian et al., 2010; Rost, 2010) to full-solid interfaces as e.g. whispering-gallery (Peng et al., 2014) and semiconductors (Bassani et al., 2004) microcavities, moving layered semiconductor structures (Artoni et al., 2001b), light-dragging effect in semiconductors (Artoni et al., 2001a, 2001b), color centers in diamond (Doherty et al., 2013; Ovartchaiyapong et al., 2014; MacQuarrie et al., 2013), bulk CuCl (single) semiconductor crystals exhibiting biexcitonic transitions (Chesi et al., 2003), crystals doped with rare-earth-metal ions or with nitrogen-vacancy color centers (Simon, 2010; Childress et al., 2014; Hausmann et al., 2014; He et al., 2006), tunable metamaterials (Wu et al., 2009a, 2009b) have laid a substantial ground for today's range of potential EIT applications in solids.

Second, recent advances in quantum information science have led to the introduction of interesting new concepts such as quantum memories, whose practical implementation involves storing, retrieval and transporting quantum information viz. “quantum states” between different nodes of a network. Photons, as a matter of fact, are promising carriers of quantum information: they are fast, robust and readily available. Atoms, on the other hand, represent reliable and long-lived storage units. Methods for manipulating photons and their quantum information in atomic media subject to EIT, as means to attain atomic quantum memories, have long been suggested (Lukin, 2003) and realized (Tsai et al., 2020; Bao et al., 2012). They essentially rely on trapping single photon Gaussian pulses in cold atomic samples by adiabatically reducing their group velocity to zero and subsequently releasing them after a suitable interval of time (*storage time*). This represents a reversible technique for coherent transfer of quantum information carried by light pulses to atoms and vice versa (Lukin, 2003). In the past few years EIT-based quantum memories have been realized also in warm atomic ensembles (Hosseini et al., 2011.) as well as in solid systems (Zhou et al., 2012). High-quality EIT-based atomic quantum memories can find interesting applications such as distributed quantum gates (Daiss et al., 2021), a building block of quantum networks, and can advance more in general high-fidelity quantum information processing. High performance EIT-based quantum memories can also be employed in quantum metrology to enhance atomic magnetometry (Bao et al., 2020), to implement distributed quantum computation (Awschalom et al., 2021), to attain color-entanglement (Viscor et al., 2012), etc.

Third, as photon-photon interaction strengths are typically very weak, powerful lasers tightly focused on nonlinear materials ought to be employed in conventional nonlinear optics to attain the required efficiency; this is a long-standing goal of technological relevance. Ultraslow light pulses in EIT media, however, may experience (Milonni, 2002) exceedingly large nonlinearities so that nonlinear optical processes may become efficient even at energy densities as low as a photon per atomic cross section (Yan et al., 2006; Wu et al., 2013). Because strong photon-photon interactions enable a number of important applications, including quantum-by-quantum control of light fields (García-Maraver et al., 2004), single-photon switches and transistors (Sun et al., 2018), all-optical deterministic quantum logic (Ottaviani et al., 2003; Rebić et al., 2004) and the realization of strongly correlated states of light and matter, EIT enabled low-light-level nonlinear optics (Chang et al., 2014) has become over the years quite a relevant and fruitful direction of investigation.

Finally, it is worth recalling that EIT can also be observed in a mechanical field, where a superconducting artificial atom is coupled to a 1D-transmission line (surface acoustic waves), which opens the possibility that superconducting circuits can be engineered to interact with acoustic fields in parameter regimes not readily accessible to purely electromagnetic systems (Andersson et al., 2020).

Analog forms of induced transparency (Section “EIT analogs”) could also be observed e.g. in optomechanical devices, where resonators are coupled to radiation pressure (Safavi-Naeini et al., 2011), or in superconducting quantum circuit architectures in the microwave regime (Gu et al., 2016; Long et al., 2018). Applications in quantum nonlinear optics as e.g., signal routing through cross-phase modulation (Schmidt and Imamoglu, 1996; Słowik et al., 2011), in reflectionless (Wu et al., 2016; Horsley et al., 2013) and anisotropic (anomalous Cherenkov emission) media (Carusotto et al., 2001) or more recently in the quantum thermodynamics of EIT heat engines (Harris, 2016; Zou et al., 2017; Zhang et al., 2021) further witness the wide-reaching perspective of the field.

Abstract

Starting from Maxwell equations and constitutive equations of a medium we consider the linear macroscopic optical response for homogeneous, isotropic, non-magnetic materials. The complex dielectric function and complex refractive index are derived with their connections with optical reflectance, transmittance and absorptance, for both unpolarized and polarized light. A few selected examples of optical response for solids (metals, semiconductors and insulators) are presented, together with the simplest classical and quantum models producing analytical expressions for the optical structures observed in experimental spectra. Analytical models give insights into optical response of materials and heterostructures, and should be used both to fit experimental data and simulate performances of electronic and photonic devices.

Key points

- Complex dielectric function.
- Complex refractive index.
- Electromagnetic waves reflection and transmission.
- Ellipsometry.
- Optical response of materials with polarized light.
- Optical spectra features and modeling.

Nomenclature

$\mathcal{A}$ (dimensionless)	Absorptance
B (T)	Magnetic induction
D (C m ⁻²)	Electric displacement
E (V m ⁻¹)	Electric field
h (J s ⁻¹)	Planck constant
H (A m ⁻¹)	Magnetic field
j (A m ⁻²)	Current density
j_{cond} (A m ⁻²)	Internal current density
j_{ext} (A m ⁻²)	External current density
k (dimensionless)	Extinction coefficient
M (A m ⁻¹)	Magnetization (magnetic moment per unit volume)
n (dimensionless)	Refractive index
$\tilde{n} = n + ik$ (dimensionless)	Complex refractive index

n_e (dimensionless)	Extraordinary refractive index
n_o (dimensionless)	Ordinary refractive index
P (C m ⁻²)	Polarization (electric dipole moment per unit volume)
q (m ⁻¹)	Wavevector
$\tilde{q} = q_1 + iq_2$	Complex wavevector
$\tilde{r}$ (dimensionless)	Reflection Fresnel coefficient
R (dimensionless)	Reflectivity
$\mathcal{R}$ (dimensionless)	Reflectance
$\tilde{t}$ (dimensionless)	Transmission Fresnel coefficient
T (dimensionless)	Transmittivity
$\mathcal{T}$ (dimensionless)	Transmittance
v (m s ⁻¹)	Phase velocity
ν (s ⁻¹)	Frequency
α (cm ⁻¹)	Absorption coefficient
αd (dimensionless)	Optical density
δ (nm)	Classical skin depth
ϵ (C ² N ⁻¹ m ⁻²)	Dielectric function
$\tilde{\epsilon} = \epsilon_1 + i\epsilon_2$	Complex dielectric function
$\epsilon_0 = 8.859 \times 10^{-12}$ C ² N ⁻¹ m ⁻²	Vacuum permittivity
ϵ_r (dimensionless)	Relative dielectric function
λ (nm)	Wavelength
$\mu_0 = 4\pi \times 10^{-7}$ T m A ⁻¹	Vacuum magnetic permeability
ρ (C m ⁻³)	External introduced charge density
σ (Ω ⁻¹ cm ⁻¹)	Optical conductivity
$\tilde{\sigma} = \sigma_1 + i\sigma_2$	Complex conductivity
Φ_B (°)	Brewster angle
χ (dimensionless)	Electrical susceptibility
$\omega = 2\pi\nu$ (s ⁻¹)	Angular frequency
$\tilde{\chi}$ (dimensionless)	Polarization state
$\tan\psi, \cos\Delta$ (dimensionless)	Ellipsometric functions

Introduction

The optical properties of materials are of major interest from both the applicative and the fundamental points of view. They are indeed quantified by macroscopic functions, such as the refractive index, the absorption coefficient and reflectivity, the knowledge of which is necessary in designing and implementing optic or optoelectronic components and devices. They give reasons of the nature of the material (e.g. allowing the distinction between metals, semiconductors and insulators), and of the material homogeneity, crystal structure and composition. Moreover, the macroscopic optical response should be related to microscopic properties, such as the electronic and vibrational structures, by means of classical models (e.g. Drude Lorentz model) and quantum treatments (e.g. for interband and intraband optical transitions).

In this article, the optical properties of macroscopic materials are described, basing only on classical arguments. Starting from Maxwell's equations in a medium, the propagation of electromagnetic (em) waves in isotropic, linear and homogeneous materials is treated. To this aim, complex macroscopic quantities as the dielectric function, the optical conductivity, the refractive index and the absorption coefficient are introduced, together with the dispersion relations which they obey. Some hints at their extensions to anisotropic and nonlinear materials are given.

The reflection and transmission properties of em waves are then analyzed at the interface between different materials, and the appropriate functions are defined for unpolarized light waves. Their extension for polarized waves follows, with the addition of the ellipsometric functions which are particularly interesting from the application point of view. Links between the different optical functions and brief hints at their measurement techniques are given. Finally, selected examples of optical spectra from the far infrared to vacuum ultraviolet are reported, together with some reliable theoretical models; these last allow best-fit of analytical expressions to the experimental spectra, determining the optical functions in terms of free-variable independent parameters.

Maxwell's equations in a medium

The theoretical framework for the optical properties of a material is given by Maxwell's equations which describe the propagation of an electromagnetic wave in a medium and which in SI units are:

$$\nabla \cdot \mathbf{D} = \rho \quad \nabla \cdot \mathbf{B} = 0$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad \nabla \times \mathbf{H} = \mathbf{j} + \frac{\partial \mathbf{D}}{\partial t} \quad (1)$$

where $\mathbf{E}$ and $\mathbf{H}$ are the electric and magnetic fields, $\mathbf{D}$ the electric displacement, $\mathbf{B}$ the magnetic induction, ρ the external introduced charge density, $\mathbf{j}$ the current density.

The relations between the electric and magnetic fields are:

$$\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P} \quad \mathbf{H} = \frac{\mathbf{B}}{\mu_0} - \mathbf{M} \quad (2)$$

where $\mathbf{P}$ is the polarization (electric dipole moment per unit volume) and $\mathbf{M}$ the magnetization (magnetic moment per unit volume), ϵ_0 and μ_0 the vacuum permittivity and magnetic permeability.

The current density $\mathbf{j}$ in the more general case contains two terms:

$$\mathbf{j} = \mathbf{j}_{ext} + \mathbf{j}_{cond} \quad (3)$$

where $\mathbf{j}_{ext}$ is the current density introduced into the medium from an external source and $\mathbf{j}_{cond}$ is the conduction current which is induced by a driving em field and which arises from the motion of charges in phase with the field (Stern, 1963; Wooten, 1972).

All these quantities are macroscopic, i.e. the average of their microscopic counterparts over a volume ΔV with small linear dimensions compared to the wavelength λ of the em wave, but large enough to contain many atoms. Then the medium can be treated as continuous from the view point of optical properties, although an ideally perfect crystal is not rigorously homogeneous on a microscopic scale. For instance, the internal charge density has crystal periodicity and varies sharply in the unit cell.

In the following, we treat with homogeneous, isotropic, non-magnetic ($\mathbf{B} = \mu_0 \mathbf{H}$) materials, and in the absence of external charges ($\rho = 0$) and currents ($\mathbf{j}_{ext} = 0$). Moreover, we consider the linear response regime, i.e. the variations in the internal charge density and in the current density induced by a driving em field of small intensity are proportional to the field. In these assumptions, the appropriate constitutive equations of the medium are:

$$\mathbf{P} = \epsilon_0 \chi \mathbf{E} \quad \mathbf{j}_{cond} = \sigma \mathbf{E} \quad (4)$$

where χ is the electric susceptibility and σ is the conductivity. The susceptibility χ and the conductivity σ contain the response of the medium to the em field $\mathbf{E}$. They both appear at the right-hand side of the last of Maxwell's Eq. (1) and represent two different currents, the conduction current $\mathbf{j}_{cond}$ and the polarization current $\mathbf{j}_{pol} = \frac{\partial \mathbf{P}}{\partial t} = \epsilon_0 \chi \frac{\partial \mathbf{E}}{\partial t}$. Since we will consider periodic solutions of Maxwell's equations, $\mathbf{j}_{cond}$ and $\mathbf{j}_{pol}$ are $\pi/2$ out of phase: $\mathbf{j}_{cond}$ is in phase with $\mathbf{E}$ and gives a time-average power absorption per unit volume $P_a = \langle \mathbf{j} \cdot \mathbf{E} \rangle = \sigma \langle \mathbf{E}^2 \rangle$; $\mathbf{j}_{pol}$, instead, is $\pi/2$ out of phase with $\mathbf{E}$ and does not provide any absorption. We stress that $\mathbf{j}_{cond}$ and $\mathbf{j}_{pol}$, and thus χ and σ , are not independent quantities because they have the same origin: the motion of charges (free or bound) induced by the em field. As it will be shown below, the real quantities χ and σ should be better represented by the real and imaginary parts of a single complex quantity. Moreover, the conductivity σ which appears in Eq. (4) is sometimes called optical conductivity, which in the limit of zero-frequency equals the usual dc electrical conductivity: for a static field $\mathbf{E}$ $\sigma \neq 0$ only in conductors, whereas for time-variable fields $\mathbf{E}(t)$ $\sigma \neq 0$ for both conductors and insulators.

An alternative parameter which characterizes a material is defined through Eq. (2) by:

$$\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P} = \epsilon_0 \mathbf{E} + \epsilon_0 \chi \mathbf{E} = \epsilon \mathbf{E} \quad (5)$$

where the quantity $\epsilon = \epsilon_0(1 + \chi)$ is termed the dielectric constant or dielectric function (as it will be evident below, the second nomenclature is more appropriate when dealing with time-dependent fields). The dimensionless quantity $\epsilon_r = \epsilon/\epsilon_0 = (1 + \chi)$ is the relative dielectric function.

ϵ and σ are the parameters which allow to completely characterize the optical response of the material: they describe the velocity of the wave in the medium and its spatial attenuation, i.e. the energy absorbed by the medium, respectively. ϵ and σ are functions of frequency (this property is called time dispersion) and wavevector (spatial dispersion) of the em wave. Moreover, they depend also on internal/external physical parameters, such as temperature, pressure, static magnetic or electric fields.

In the aforementioned hypotheses and from Maxwell's equations, the following wave equation can be derived:

$$\nabla^2 \mathbf{E} = \epsilon_r \epsilon_0 \mu_0 \frac{\partial^2 \mathbf{E}}{\partial t^2} + \sigma \mu_0 \frac{\partial \mathbf{E}}{\partial t} \quad (6)$$

This is the so-called d'Alembert equation for a wave propagating in a generic absorbing medium. Solutions of Eq. (6) are necessarily restricted to transverse waves because $\nabla \cdot \mathbf{E} = 0$ in the absence of a net charge density ρ . In vacuum ($\epsilon_r = 1$, $\sigma = 0$) the wave velocity coincides with the velocity of light $c = (\sqrt{\epsilon_0 \mu_0})^{-1}$, while in a non-absorbing medium ($\sigma = 0$) the phase velocity is $v = (\sqrt{\epsilon_r \epsilon_0 \mu_0})^{-1} = c/\sqrt{\epsilon_r} = c/n$, where $n = \sqrt{\epsilon_r} = c/v$ is the refractive index of the medium. The wave amplitude attenuation is described by the second term on the right of Eq. (6).

The complex dielectric function

It must be emphasized that, in the case of time-dependent em fields, there will generally be a phase shift between the motion of the charge carriers and the electric field $\mathbf{E}$ (similarly to what happens in ac circuits). In such cases the complex formalism is particularly

convenient to describe phase shifts, and in addition to describe dispersion and absorption effects at the same time (Stern, 1963). Complex fields are usually defined, the real parts of which have physical meaning and are the ones involved in Maxwell's equations. For instance, $\mathbf{E}(\mathbf{r}, t) = \text{Re} [\tilde{\mathbf{E}}(\mathbf{r}, t)]$, where the tilde distinguishes the complex quantity from its real counterpart.

Since the experimental measurements of the optical properties of solids are usually conducted with monochromatic light, we will consider a solution of Eq. (6) in the form of a monochromatic plane wave:

$$\tilde{\mathbf{E}}(\mathbf{r}, t) = \tilde{\mathbf{E}}_0 \exp [i(\tilde{\mathbf{q}} \cdot \mathbf{r} - \omega t)] \quad (7)$$

where $\tilde{\mathbf{E}}$ is the complex electric field, $\tilde{\mathbf{E}}_0 = \mathbf{E}_0 e^{i\varphi_0}$ is the polarization vector with arbitrary phase φ_0 , $\mathbf{r}$ is the position vector with respect to an arbitrary coordinate system, $\omega = 2\pi\nu$ is the angular frequency, and $\tilde{\mathbf{q}} = \mathbf{q}_1 + i\mathbf{q}_2$ is the complex wavevector of the em wave in the medium. The absolute value of the wavevector in vacuum is $q = 2\pi/\lambda = \omega/c$. In fact, $\tilde{\mathbf{q}}$ describes the phase and spatial attenuation of the em wave, its explicit form being written as:

$$\begin{aligned} \mathbf{E}(\mathbf{r}, t) &= \text{Re} \tilde{\mathbf{E}}(\mathbf{r}, t) = \text{Re} [\tilde{\mathbf{E}}_0 \exp [i(\tilde{\mathbf{q}} \cdot \mathbf{r} - \omega t)]] = \\ &= \text{Re} [\tilde{\mathbf{E}}_0 \exp [i(\mathbf{q}_1 \cdot \mathbf{r} - \omega t)]] \exp (-\mathbf{q}_2 \cdot \mathbf{r}) \\ &= \mathbf{E}_0 \cos (\mathbf{q}_1 \cdot \mathbf{r} - \omega t + \varphi_0) \exp (-\mathbf{q}_2 \cdot \mathbf{r}) \end{aligned} \quad (8)$$

In fact, $\mathbf{q}_1$ and $\mathbf{q}_2$ are perpendicular to the constant phase planes and to the constant amplitude planes, respectively. If $\mathbf{q}_1/\mathbf{q}_2$, the wave is homogeneous, otherwise it is referred as inhomogeneous (Born and Wolf, 1980).

By inserting the monochromatic plane wave expression Eq. (7) in Eq. (6) the wave dispersion relation is obtained:

$$\tilde{\mathbf{q}} \cdot \tilde{\mathbf{q}} = \mu_0 \left(\varepsilon + i \frac{\sigma}{\omega} \right) \omega^2 = \mu_0 \tilde{\varepsilon} \omega^2 \quad (9)$$

where a complex dielectric function $\tilde{\varepsilon}$ has been introduced as:

$$\tilde{\varepsilon} \equiv \varepsilon_1 + i\varepsilon_2 = \varepsilon + i \frac{\sigma}{\omega} \quad (10)$$

The real part $\varepsilon_1 = \varepsilon$ describes the wave dispersion whereas the imaginary part $\varepsilon_2 = \sigma/\omega$ accounts for the dissipation of energy by the material. Alternatively, the complex conductivity $\tilde{\sigma} \equiv \sigma_1 + i\sigma_2 = -i\omega\tilde{\varepsilon} = \sigma - i\omega\varepsilon$ is sometimes used instead of $\tilde{\varepsilon}$.

The possibility of a phase shift between $\tilde{\mathbf{D}}$ (or $\tilde{\mathbf{j}}$) and $\tilde{\mathbf{E}}$ is now easily included by defining $\tilde{\mathbf{D}} = \tilde{\varepsilon} \tilde{\mathbf{E}}$ (or $\tilde{\mathbf{j}} = \tilde{\sigma} \tilde{\mathbf{E}}$). Moreover, when considering an em field given by Eq. (7), the displacement current $\partial\mathbf{D}/\partial t$ and the conduction current $\mathbf{j}_{cond}$ which appear in Maxwell's equations can be combined as follows:

$$\mathbf{j}_{cond} + \frac{\partial\mathbf{D}}{\partial t} = \sigma\mathbf{E} + \varepsilon \frac{\partial\mathbf{E}}{\partial t} = \text{Re} [(\sigma - i\omega\varepsilon)\tilde{\mathbf{E}}] = \text{Re} [\tilde{\sigma}\tilde{\mathbf{E}}] = \text{Re} [-i\omega\tilde{\varepsilon}\tilde{\mathbf{E}}] \quad (11)$$

Thus the response function $\tilde{\varepsilon}$ accounts not only for the displacement current $\partial\mathbf{D}/\partial t$, which is $\pi/2$ out-of-phase with $\mathbf{E}$ and does not dissipate energy, but also, in its imaginary part, for the conduction current $\mathbf{j}_{cond}$, which is in phase with $\mathbf{E}$ and dissipates energy. The same holds for $\tilde{\sigma}$. When the optical response of a medium is calculated according to a specific model, either $\tilde{\varepsilon}$ or $\tilde{\sigma}$ must be introduced (but not both), since each one already includes both the in-phase and out-of-phase components.

In a general treatment, ε and σ are functions of space and time since the space-time representation of Maxwell's equations has been adopted. They are response functions or linear integral operators that connect the fields $\mathbf{D}(\mathbf{r}, t)$ and $\mathbf{j}(\mathbf{r}, t)$ with the electric field $\mathbf{E}(\mathbf{r}', t')$ at all other positions and all earlier times. Thus, in general, (Wooten, 1972):

$$\mathbf{D}(\mathbf{r}, t) = \int d\mathbf{r}' \int_{-\infty}^t \varepsilon(\mathbf{r}, \mathbf{r}', t, t') \mathbf{E}(\mathbf{r}', t') dt' \quad (12)$$

i.e. $\mathbf{D}(\mathbf{r}, t)$ and $\mathbf{E}(\mathbf{r}, t)$ are not proportional each to other, whereas this is true for their Fourier components. In fact, fields and sources should be decomposed into a complete set of monochromatic plane waves, for example:

$$\mathbf{E}(\mathbf{r}, t) = \int d\mathbf{q} \int_{-\infty}^{+\infty} \tilde{\mathbf{E}}(\mathbf{q}, \omega) \exp [i(\mathbf{q} \cdot \mathbf{r} - \omega t)] d\omega \quad (13)$$

where $\tilde{\mathbf{E}}(\mathbf{q}, \omega)$ is the Fourier transform of $\mathbf{E}(\mathbf{r}, t)$, with:

$$\tilde{\mathbf{E}}(\mathbf{q}, \omega) = \left(\frac{1}{2\pi} \right)^4 \int d\mathbf{r} \int_{-\infty}^{+\infty} \mathbf{E}(\mathbf{r}, t) \exp [-i(\mathbf{q} \cdot \mathbf{r} - \omega t)] dt \quad (14)$$

Operating the Fourier transform of Eq. (12) and utilizing the convolution theorem, one obtains:

$$\tilde{\mathbf{D}}(\omega, \mathbf{q}) = \tilde{\varepsilon}(\omega, \mathbf{q}) \tilde{\mathbf{E}}(\omega, \mathbf{q}) \quad (15)$$

where the complex dielectric function $\tilde{\varepsilon}(\omega, \mathbf{q})$, Fourier transform of $\varepsilon(\mathbf{r}, t)$, shows up as the proportionality constant between the complex field components. An analogous relation $\tilde{\mathbf{j}}(\omega, \mathbf{q}) = \tilde{\sigma}(\omega, \mathbf{q}) \tilde{\mathbf{E}}(\omega, \mathbf{q})$ can be obtained.

The frequency and wavevector dependence of $\tilde{\varepsilon}(\omega, \mathbf{q})$ and $\tilde{\sigma}(\omega, \mathbf{q})$ describe the time and the spatial dispersion of the material, respectively (Melrose and Mc Phedran, 1991). The spatial dispersion is associated to the presence of natural lengths in the medium, such as the dimension of atoms and inter-atomic spacings; its effect is weak for wavelengths which are long as compared to the

natural lengths. In the optical spectral range the spatial dispersion should be neglected and $\tilde{\epsilon}(\omega, \mathbf{q}) = \tilde{\epsilon}(\omega)$; this is not possible at X-ray wavelengths. Moreover, we note that the wave dispersion relation (Eq. 9), which bounds ω and $\tilde{\mathbf{q}}$, does not imply in general a connection between time dispersion and spatial dispersion. In principle, it is possible to investigate separately the temporal response of a medium (and hence the time dispersion in ω) by subjecting it to a spatially uniform field that oscillates in time, or the spatial response (and hence the spatial dispersion in $\tilde{\mathbf{q}}$) with a static field that is spatially periodic.

In an anisotropic medium the polarization $\mathbf{P}$ and $\mathbf{j}_{cond}$ generally lie in a direction different from that of $\mathbf{E}$ (Wooten, 1972). This situation can be handled by representing the complex dielectric function as a tensor $\tilde{\epsilon}_{ij}$. The real and imaginary parts of $\tilde{\epsilon}_{ij}$ are symmetric also for an anisotropic medium, thus it is possible to put each of them into diagonal form in an appropriate set of coordinate axes (principal axes). The two sets do not coincide in general, until the crystal has symmetry at least as high as orthorhombic. In the particular case of cubic crystal symmetry, $\tilde{\epsilon}_{ij}$ reduces to a scalar quantity.

In a nonlinear dielectric medium, it is possible to expand the relation between $\mathbf{P}$ and $\mathbf{E}$ in a Taylor series about $\mathbf{E} = 0$. Thus $\mathbf{P} = \epsilon_0 (\chi \mathbf{E} + \chi^{(2)} \mathbf{E}^2 + \chi^{(3)} \mathbf{E}^3 + \dots)$ where the $\chi^{(n)}$ coefficient describes the n -th order nonlinear effect. Eq. (6) is not applicable to em waves in nonlinear media. However, Maxwell's equations can be used to derive a nonlinear partial differential equation that these waves obey.

Finally, the real and imaginary parts of $\tilde{\epsilon}$ are not independent quantities, being related one to other by the integral relations, the so called Kramers-Kronig relations (Smith, 1985). These relations follow rigorously from the requirement of causality (i.e., there can be no effect before the cause) and apply to the real and imaginary part of whatever linear response function. Thus, the complex dielectric function $\tilde{\epsilon}(\omega)$ obeys the following relations:

$$\begin{aligned}\epsilon_1(\omega) &= \epsilon_0 + \frac{2}{\pi} P \int_0^\infty \frac{\omega' \epsilon_2(\omega')}{\omega'^2 - \omega^2} d\omega' \\ \epsilon_2(\omega) &= -\frac{2\omega}{\pi} P \int_0^\infty \frac{\epsilon_1(\omega') - \epsilon_0}{\omega'^2 - \omega^2} d\omega'\end{aligned}\quad (16)$$

where P stands for the principal value of the integral.

We remind that $\tilde{\epsilon}$ and $\tilde{\sigma}$ describe macroscopic properties of materials, but they can be related to polarizabilities on the atomic scale and give reasons of microscopic properties of condensed matter, e.g. electronic and vibrational structures.

Complex refractive index

In analogy with the statement $n^2(\omega) = \epsilon_r(\omega)$ valid in non-absorbing media, where n is the refractive index, it is useful to define a complex quantity, the so called complex refractive index $\tilde{n}(\omega)$ that is related to the relative complex dielectric function $\tilde{\epsilon}_r(\omega) = \tilde{\epsilon}(\omega)/\epsilon_0$ by the relation:

$$\tilde{n}^2(\omega) = \tilde{\epsilon}_r(\omega) \quad (17)$$

The real part of $\tilde{n}(\omega)$ coincides with the usual refractive index whereas the imaginary part is the extinction coefficient of the medium (Christy, 1972; Wooten, 1972). Thus:

$$\tilde{n}(\omega) = n(\omega) + ik(\omega) \quad (18)$$

and then the real and imaginary part of $\tilde{\epsilon}_r$, including absorption contribution, should be written as:

$$\epsilon_{r1} = n^2 - k^2 \quad \epsilon_{r2} = 2nk \quad (19)$$

Also, the inverse relations should be derived:

$$n = \left\{ \frac{1}{2} \left[\epsilon_{r1} + (\epsilon_{r1}^2 + \epsilon_{r2}^2)^{1/2} \right] \right\}^{1/2} \quad k = \frac{\epsilon_{r2}}{2n} \quad (20)$$

The dispersion relation of Eq. (9) assumes the following expression:

$$\tilde{\mathbf{q}} \cdot \tilde{\mathbf{q}} = \mu_0 \tilde{\epsilon} \omega^2 = \mu_0 \epsilon_0 \tilde{\epsilon}_r \omega^2 = \frac{\omega^2}{c^2} \tilde{n}^2 \quad (21)$$

If the wave is homogeneous, i.e. $\mathbf{q}_1 \parallel \mathbf{q}_2$, it holds $\tilde{\mathbf{q}} = \frac{\omega}{c} \tilde{n} \mathbf{u}_q$, where $\mathbf{u}_q$ is the unit vector parallel to $\tilde{\mathbf{q}}$, and then $\mathbf{q}_1 = \frac{\omega}{c} n \mathbf{u}_q$, $\mathbf{q}_2 = \frac{\omega}{c} k \mathbf{u}_q$. Thus Eq. (7) should be written as:

$$\tilde{\mathbf{E}}(\mathbf{r}t) = \tilde{\mathbf{E}}_0 \exp \left[-\frac{\omega}{c} k \mathbf{u}_q \cdot \mathbf{r} \right] \cdot \exp \left[i \left(\frac{\omega}{c} n \mathbf{u}_q \cdot \mathbf{r} - \omega t \right) \right] \quad (22)$$

The extinction coefficient k measures the attenuation of the wave amplitude with the propagation distance inside the medium, while n determines the phase velocity c/n in the medium. The penetration depth δ or classical skin depth, defined as the distance at which the field amplitude drops of $1/e$, is $\delta = c/(\omega k)$.

In anisotropic material, $\tilde{n}(\omega)$ is no more a scalar quantity, and as it is stated for $\tilde{\epsilon}$, it should be a tensor. For example, in a uniaxial crystal (i.e. $\tilde{\epsilon}_{xx} = \tilde{\epsilon}_{yy} \neq \tilde{\epsilon}_{zz}$) ordinary (n_o) and extraordinary (n_e) refractive indexes are defined, for light propagation in the xy plane and along the z direction, respectively.

Just as ϵ_1 and ϵ_2 , also n and k satisfy Kramers-Kronig relations.

An additional important macroscopic quantity of the medium is the absorption coefficient α , which describes the relative decrease in the wave intensity I with unit distance (in the propagation direction, i.e. $u_q//dr$). Since the wave intensity (i.e. the power which is incident on the unit area perpendicular to u_q) is $I = n c \varepsilon_0 E^2 / 2$, from Eq. (22) it follows:

$$\alpha(\omega) = \frac{2 k \omega}{c} = \frac{4 \pi k}{\lambda} = \frac{\omega \varepsilon_{r2}}{n c} \quad (23)$$

The exponential attenuation of I after a propagating distance d accounts for the phenomenological Lambert-Beer law:

$$I = I_0 e^{-\alpha d} \quad (24)$$

where I_0 is the incident wave intensity. Differently from n and k , α is a dimensional quantity usually measured in cm^{-1} . The αd coefficient that reflects both the physical chemical properties and the geometry of the medium is referred to as optical density.

Reflection and transmission properties

Unpolarized light

While the refractive index n is measurable with a high degree of accuracy through experimental techniques that do not require absolute intensity measurements, such as minimum deviation, Brewster angle and interferometric techniques, the complete determination of n and k (or α) of a medium generally requires the measurement of the intensity reflected I_r , transmitted I_t and/or absorbed I_a with respect to the intensity I_0 of an em wave incident on the material surface. From the energy conservation law it follows:

$$I_0 = I_r + I_t + I_a \quad (25)$$

Dividing both sides by I_0 , one obtains:

$$\mathcal{R} + \mathcal{T} + \mathcal{A} = 1 \quad (26)$$

where $\mathcal{R}$, $\mathcal{T}$ and $\mathcal{A}$ are the reflectance, the transmittance and the absorbance of the medium, respectively. The connection between these quantities and the optical functions of the medium can be obtained by Maxwell's equations with appropriate surface boundary conditions, i.e. the tangential components of $\mathbf{E}$ and $\mathbf{H}$ and the normal components of $\mathbf{D}$ and $\mathbf{B}$ at the surface of the material are continuous.

Hereafter, we only deal with specularly reflected light: this condition is well matched when surface irregularities and roughness have length scales much smaller than the light wavelength λ . In this case diffuse reflection losses are negligible.

Consider the simplest case of a plane monochromatic wave, propagating in a medium with refractive index $\tilde{n}_0$, which is normally incident on the surface of a semi-infinite medium with refractive index $\tilde{n}$ giving rise to the phenomena of reflection and refraction. Applying the boundary conditions both to the electric field $\mathbf{E}$ and to the magnetic field $\mathbf{H}$ (with $\mathbf{E} = \mu_0 \mathbf{H} \times \mathbf{v}$ in a transverse electromagnetic wave), the tangential components of the incident (0), reflected (r) and refracted (i.e. transmitted, t) fields must obey (Hecht, 2014):

$$\begin{aligned} \tilde{E}_t &= \tilde{E}_0 + \tilde{E}_r \\ \tilde{n} \tilde{E}_t &= \tilde{n}_0 \tilde{E}_0 - \tilde{n}_0 \tilde{E}_r \end{aligned} \quad (27)$$

By solving for $\tilde{E}_r$ and $\tilde{E}_t$, one has:

$$\tilde{r} = \frac{\tilde{E}_r}{\tilde{E}_0} = \frac{\tilde{n}_0 - \tilde{n}}{\tilde{n}_0 + \tilde{n}} \quad \tilde{t} = \frac{\tilde{E}_t}{\tilde{E}_0} = \frac{2\tilde{n}_0}{\tilde{n}_0 + \tilde{n}} \quad (28)$$

where $\tilde{r}$ and $\tilde{t}$ are complex quantities in the more general case, and are named reflection and transmission Fresnel coefficients, respectively. Then, the reflected and transmitted waves change in amplitude and phase with respect to the incident one, and while $\tilde{r}$ changes only in sign inverting the propagation direction, $\tilde{t}$ changes the absolute value. We note that $\tilde{t} = 1 + \tilde{r}$ and $\tilde{t}$ value should exceed unity. Moreover, in transparent media (n_0 and n real) the phase change in reflection is π when $n_0 < n$.

At the interface of the two media, the reflected and transmitted intensity relative to the incident one are called reflectivity R and transmittivity T , and are given by:

$$\begin{aligned} R &= \frac{I_r}{I_0} = |\tilde{r}|^2 = \left| \frac{\tilde{n}_0 - \tilde{n}}{\tilde{n}_0 + \tilde{n}} \right|^2 = \frac{(n - n_0)^2 + (k - k_0)^2}{(n + n_0)^2 + (k + k_0)^2} \\ T &= \frac{I_t}{I_0} = \text{Re} \left(\frac{\tilde{n}}{\tilde{n}_0} \right) |\tilde{t}|^2 = \text{Re} \left(\frac{\tilde{n}}{\tilde{n}_0} \right) \left| \frac{2\tilde{n}_0}{\tilde{n}_0 + \tilde{n}} \right|^2 \end{aligned} \quad (29)$$

We note that R and T are ≤ 1 with $R + T = 1$, as expected by the energy conservation at the interface between different media.

When considering the reflection, absorption, and transmission properties of optical materials, care must be taken to differentiate between reflectivity and reflectance, transmittivity and transmittance. To make the distinction between these terms clear, let us consider a sample of material with $\tilde{n}$ and thickness d , immersed in air ($\tilde{n}_0 = 1$), as shown in Fig. 1. Coming from air, the

Fig. 1 Reflected and transmitted beams generated by an em wave with intensity I_0 near-normally incident on a layer with complex refractive index $\tilde{n}$ immersed in air. Refracted and reflected angles are exaggerated for clearness.

near-normally incident beam is split into reflected and transmitted fractions (as determined by R and T) at each interface, giving rise to secondary beams: reflectance and transmittance are obtained by summing up all the multiple-reflected and multiple-transmitted elements, which account also for light absorption along the thickness d . The total intensity reflected from the front surface is

$$I_r = I_{r1} + I_{r2} + \dots + I_{rm} + \dots = (R + R T^2 e^{-2\alpha d} + R^3 T^2 e^{-4\alpha d} + \dots) I_0 \quad (30)$$

Then, since $T = 1 - R$, the reflectance R is

$$\mathcal{R} = \frac{I_r}{I_0} = R + \frac{(1 - R)^2 R e^{-2\alpha d}}{1 - R^2 e^{-2\alpha d}} \quad (31)$$

Similarly the transmittance $\mathcal{T}$ results

$$\mathcal{T} = \frac{(1 - R)^2 e^{-\alpha d}}{1 - R^2 e^{-2\alpha d}} \quad (32)$$

and the absorbance $\mathcal{A} = 1 - \mathcal{R} - \mathcal{T}$ is equal to:

$$\mathcal{A} = \frac{(1 - R) (1 - e^{-\alpha d})}{1 - R e^{-\alpha d}} \quad (33)$$

In the only case that the optical density $\alpha d \gg 1$, the reflectance $\mathcal{R}$ has only the first term in Eq. (31) and coincides with the reflectivity R of the material; there is no more intensity transmitted. If the thickness of the sample is sufficiently low to allow transmittance, $\mathcal{T}$ depends on α , d and R .

Polarized light

In order to evaluate the Fresnel coefficients in the general case of a plane wave propagating in a medium with refractive index $\tilde{n}_0$ and incident at an angle ϕ_0 on a semi-infinite medium with refractive index $\tilde{n}$, it is convenient to consider separate cases with the electric vector polarized perpendicular to and parallel to the plane of incidence (Azzam and Bashara, 1977 and Aspnes, 1985). There is no loss of generality in doing so, since any electric or magnetic vector may be resolved into components normal to- and parallel to- this plane. The subscripts s and p are usually refer to the normal and parallel component, respectively.

The electric field $\tilde{E}_0(\mathbf{r}, t)$ associated to an incident plane wave propagating in the z direction of a local coordinate system xyz (Fig. 2) can be represented as:

$$\tilde{E}_0(\mathbf{r}, t) = \text{Re} \{ (\mathbf{i} \tilde{E}_{0p} + \mathbf{j} \tilde{E}_{0s}) \exp [i(\tilde{\mathbf{q}} \cdot \mathbf{r} - \omega t)] \} \quad (34)$$

where $\tilde{E}_{0p}$ and $\tilde{E}_{0s}$ are the complex field components of $\tilde{E}_0$ that describe both amplitude and phase dependence along the x (p direction) and y (s direction) axes of the system. The electric field of the reflected wave can be represented in another local coordinate system as:

$$\tilde{E}_r(\mathbf{r}', t) = \text{Re} \{ (\mathbf{i}' \tilde{r}_p \tilde{E}_{rp} + \mathbf{j}' \tilde{r}_s \tilde{E}_{rs}) \exp [i(\tilde{\mathbf{q}}' \cdot \mathbf{r}' - \omega t)] \}. \quad (35)$$

Fig. 2 Reflection of an em wave from a surface. The field components E_s and E_p are shown, together with the coordinate axes for the incident and reflected waves. The plane of incidence contains the incoming wavevector $\mathbf{q}$ and the specularly outgoing $\mathbf{q}'$, as well as the surface normal.

An analogous expression holds for the transmitted electric field. As in the previous case, by imposing the surface boundary conditions for the electric and magnetic fields at the interface, the complex Fresnel coefficients in reflection ($\tilde{r}_p$ and $\tilde{r}_s$) and transmission ($\tilde{t}_p$ and $\tilde{t}_s$) are obtained:

$$\begin{aligned}\tilde{r}_p &= \frac{\tilde{E}_{rp}}{\tilde{E}_{0p}} = \frac{\tilde{n}_0 \cos \tilde{\varphi} - \tilde{n} \cos \tilde{\varphi}_0}{\tilde{n}_0 \cos \tilde{\varphi} + \tilde{n} \cos \tilde{\varphi}_0} & \tilde{t}_p &= \frac{\tilde{E}_{tp}}{\tilde{E}_{0p}} = (1 + \tilde{r}_p) \frac{\cos \tilde{\varphi}_0}{\cos \tilde{\varphi}} \\ \tilde{r}_s &= \frac{\tilde{E}_{rs}}{\tilde{E}_{0s}} = \frac{\tilde{n}_0 \cos \tilde{\varphi}_0 - \tilde{n} \cos \tilde{\varphi}}{\tilde{n}_0 \cos \tilde{\varphi}_0 + \tilde{n} \cos \tilde{\varphi}} & \tilde{t}_s &= \frac{\tilde{E}_{ts}}{\tilde{E}_{0s}} = 1 + \tilde{r}_s\end{aligned}\quad (36)$$

where $\tilde{\varphi}_0$ and $\tilde{\varphi}$ are the incident and refraction complex angles which are no more purely geometrical quantities. The refracted em wave is generally inhomogeneous, i.e. it is characterized by different directions for planes of constant amplitude (parallel to the interface and perpendicular to $\mathbf{q}_2$) and for planes of constant phase (perpendicular to $\mathbf{q}_1$). In particular, the generalized Snell law at the interface between two absorbing media is written as:

$$\tilde{n}_0 \sin \tilde{\varphi}_0 = \tilde{n} \sin \tilde{\varphi} \quad (37)$$

If the ambient medium is transparent, such as vacuum or air, the quantity $n_0 \sin \varphi_0 = \tilde{n} \sin \tilde{\varphi}$ is real, and then $\tilde{\varphi}$ is determined starting from $\tilde{n}$ and $\tilde{\varphi}_0$. At normal incidence the distinction between parallel and perpendicular components disappears and $\tilde{r}_s = \tilde{r}_p = \tilde{r}$ and $\tilde{t}_s = \tilde{t}_p = \tilde{t}$, i.e. Eq. (36) reduce to Eq. (28).

From the Fresnel coefficients in Eq. (36) and the energy conservation at the interface, reflectivity R_j and transmittivity T_j ($j = s, p$) are derived as:

$$R_j = |\tilde{r}_j|^2 \quad T_j = \operatorname{Re} \left(\frac{\tilde{n} \cos \tilde{\varphi}}{\tilde{n}_0 \cos \tilde{\varphi}_0} \right) |\tilde{t}_j|^2 \quad (38)$$

Again it is verified that $R_s + T_s = 1$ and $R_p + T_p = 1$. At normal incidence Eq. (38) reduce to Eq. (29). In case of unpolarized waves, it holds:

$$R = \frac{1}{2} (R_p + R_s) \quad T = \frac{1}{2} (T_p + T_s) \quad (39)$$

At any angle of incidence φ_0 (except for $\varphi_0 = 0$ or $\varphi_0 = \pi/2$) it is $R_s > R_p$. Moreover, when both materials are transparent ($k_0 = k = 0$), and when $\varphi_0 + \varphi = \pi/2$ (i.e. the reflected and refracted waves are perpendicular) it follows that $R_p = 0$. The p component is refracted without losses, while the s component is only partially refracted. This particular value of φ_0 is called Brewster angle ϕ_B and from the Snell law it follows $\tan \phi_B = n/n_0$. In Fig. 3 R_p and R_s components vs the angle of incidence for bulk silicon immersed in air and in the transparent wavelength region ($n \cong 3.42$) are reported. The Brewster angle value is $\phi_B \cong 73.7^\circ$. If $k \neq 0$ R_p goes through a non-zero minimum in correspondence of a different value of $\varphi > \phi_B$ which is called pseudo-Brewster angle.

Ellipsometric functions

An alternative way to describe the optical response of a material is based on the variation of the state of polarization of an em wave produced by reflection on the surface. The polarization state of an em wave is expressed by $\tilde{\chi}$, defined as (Azzam and Bashara, 1977 and Aspnes, 1985):

Fig. 3 Polarized reflectivities R_s and R_p as a function of the angle of incidence for Silicon in the subgap transparency spectral region ($n = 3.42$). R_p reaches zero value at the Brewster angle $\phi_B = 73.7^\circ$.

$$\tilde{\chi} = \frac{\tilde{E}_p}{\tilde{E}_s} \quad (40)$$

Since $\tilde{E}_p$ and $\tilde{E}_s$ are complex, $\tilde{\chi}$ is in general a complex quantity: if $\tilde{E}_p$ and $\tilde{E}_s$ are in phase, $\tilde{\chi}$ is real and the em wave is linearly polarized. In the case of $\tilde{E}_p$ and $\tilde{E}_s$ are $\pi/2$ out of phase, $\tilde{\chi}$ is purely imaginary; if, in addition, $|\tilde{E}_p| = |\tilde{E}_s|$ then $\tilde{\chi} = \pm i$ and the wave is circularly polarized. Elliptical polarization is obtained when $\tilde{E}_p$ and $\tilde{E}_s$ are out of phase by $\pi/2$ and have different amplitudes, or in the more general case when the phase angle has any value different from 0 and $\pi/2$.

The incident and reflected waves are characterized by the polarization states $\tilde{\chi}_0$ and $\tilde{\chi}_r$, respectively, that are connected by the following relationship:

$$\tilde{\chi}_r = \frac{\tilde{E}_{rp}}{\tilde{E}_{rs}} = \frac{\tilde{r}_p \tilde{E}_{0p}}{\tilde{r}_s \tilde{E}_{0s}} = \frac{\tilde{r}_p}{\tilde{r}_s} \tilde{\chi}_0 \quad (41)$$

where $\tilde{r}_p$ and $\tilde{r}_s$ are defined by Eq. (36). Since $\tilde{r}_p$ and $\tilde{r}_s$ are complex quantities (i.e. $\tilde{r} = |\tilde{r}| e^{i\theta}$), it is evident that the reflected wave has a different polarization state with respect to the incident one.

When linearly polarized light impinges on a material surface, the reflected light is generally elliptically polarized. This ellipse of polarization is completely characterized by the ratio of the two axes and by the orientation of the major axis. From this fact the name ellipsometry is given to the experimental technique which allows to determine the variation in polarization state by reflection on a sample surface.

In ellipsometry the crucial quantity is the ratio $\tilde{\rho}$, defined as the ratio between $\tilde{\chi}_r$ and $\tilde{\chi}_0$:

$$\begin{aligned} \tilde{\rho} &= \frac{\tilde{\chi}_r}{\tilde{\chi}_0} = \frac{\tilde{r}_p}{\tilde{r}_s} = \\ &= \left(\frac{E_{rp}}{E_{rs}} \right) \left(\frac{E_{0s}}{E_{0p}} \right) \exp \left\{ i \left[\left(\beta_p - \beta_s \right)_r - \left(\beta_p - \beta_s \right)_0 \right] \right\} \end{aligned} \quad (42)$$

Here $(\beta_p - \beta_s)$ is the phase difference between p and s field components. The absolute value of $\tilde{\rho}$ gives information on the amplitude ratio of reflected to incident E_p and E_s , whereas the phase of $\tilde{\rho}$ is given by the variation of the phase difference caused by reflection. The quantity $\tilde{\rho}$ is usually written in the compact form:

$$\tilde{\rho} = \tan \psi e^{i\Delta} \quad (43)$$

where

$$\tan \psi = \rho = \frac{|\tilde{r}_p|}{|\tilde{r}_s|} = \frac{r_p}{r_s} \quad \Delta = \left(\beta_p - \beta_s \right)_r - \left(\beta_p - \beta_s \right)_0 \quad (44)$$

A single ellipsometric measurement gives $\tilde{\rho}$, i.e. the ellipsometric functions $\tan \psi$ and $\cos \Delta$, which allow to determine the optical properties of a material. As an example, in the case of a semi-infinite material with complex dielectric function $\tilde{\varepsilon}$, assuming that the ambient medium is void ($\tilde{\varepsilon}_0 = 1$) and ϕ_0 is the angle of incidence, it is possible to obtain a simple relation which bounds $\tilde{\rho}$ and $\tilde{\varepsilon}$:

$$\tilde{\varepsilon} = \sin^2 \phi_0 + \sin^2 \phi_0 \tan^2 \phi_0 \left| \frac{1 - \tilde{\rho}}{1 + \tilde{\rho}} \right|^2 \quad (45)$$

It is then immediate to derive the real and imaginary part of $\tilde{\varepsilon} = \varepsilon_1 + i\varepsilon_2$. In addition, in transparent media, ellipsometry is widely used to determine the refractive index and the thickness of a thin film layer deposited on a substrate with known optical properties.

We note that the reflection/absorption/transmission properties of a medium are of major interest from the application point of view. Moreover, they allow a complete optical characterization of a homogeneous, isotropic medium, i.e. the determination of ε_1 and ε_2 or n and k . Since there are two unknown parameters, at least two independent measurements are needed. In transparent materials, R and T should be used, or R measurements at different angles of incidence. In semi-infinite media (or with finite thickness but opaque) only reflection and ellipsometric measurements should be performed.

Moreover, the Fresnel coefficient $\tilde{r} = |\tilde{r}| e^{i\theta}$ expresses the linear relation between incident and reflected electric field amplitudes which obey causality. As stated above, it follows that a dispersion relation exists which connects its real and imaginary parts. Using the normal incidence reflectivity $R = |\tilde{r}|^2$, the dispersion relation between the absolute value R and the phase angle θ should be written as (Smith, 1985):

$$\theta(\omega) = -\frac{\omega}{\pi} P \int_0^\infty \frac{\ln R(\omega')}{\omega'^2 - \omega^2} d\omega' \quad (46)$$

Then θ should be determined, in principle, at whatever frequency if $R(\omega)$ is known over the whole spectral interval. In practice, $R(\omega)$ is measured over a finite spectral range and some means of extrapolating experimental results over inaccessible spectral ranges are necessary. Finally, n and k are calculated on the basis of Eqs. (28) and (29).

Optical spectra and theoretical models: Selected examples

Optical spectra

A lot of optical spectra articles and data collections have been published by different authors, regarding different spectral intervals and material samples. The “Handbook of Optical Constant of Solids” (Palik, 1985) has been the first systematic and critical database which tabulated n and k values over the widest spectral range (ideally from X-rays to microwaves), depending on literature availability, for a large number of materials of technological and physical interest: 37 materials have been examined by several authors, and the critiques for each materials have been preceded by 11 chapter articles that discuss various aspects of optical response, with some emphasis on experimental techniques and sample preparation. This handbook has been followed by a second volume (Palik, 1991), including 43 new materials, and by the handbook of Adachi (1999).

In the following we report on a few examples of the optical response, most of all on semiconductor materials for these reasons:

- (a) semiconductor materials present characteristics intermediate between metals and insulators: in the case of heavily doping they may reach an optical conductivity approaching that of metals, on the contrary they behave like an insulator when fundamental energy gap is very large (above 3 eV);
- (b) they are the most important materials for technological applications, in particular being the main components not only of micro/nanoelectronics devices, but also of photonic devices such as lasers, LED, photodetectors and imaging, solar cells, optical computers;
- (c) the optical functions of semiconductors considerably change in controlled way—and are precisely tunable—as a function of: order/disorder in the crystal structure (monocrystals, polycrystals, amorphous); doping; external perturbations (temperature, electric or magnetic fields, pressure, strain, electromagnetic radiations); surface conditions (specular, rough, with oxides or overlayers).

Here we will focus on the optical response of materials as obtained with linear spectroscopic techniques and on the simpler interpretative models, both classical and quantum. An advanced discussion on the optical properties of dielectrics and semiconductors (including magneto- and electro-optical effects, metamaterials, photoluminescence, quasi-particles and non-linear optics) is presented elsewhere (Ivchenko, 2023).

The determination of the optical functions of semiconductors at and beyond the fundamental absorption edge is a powerful tool in studying their electronic band structure, whereas at lower energies it gives information on the vibrational structure and free carriers concentration. To this purpose, reliable physical models with analytical expressions for the optical functions in terms of free-variable parameters are adopted in the fit by least-square regression to experimental data on limited spectral intervals. As a result, physically significant parameter values are a direct outcome of the analysis, including e.g.: (a) parameters that describe the optical functions, the most important being the energies of the optical gap E_g of interband optical transitions and of the vibrational modes (phonons); (b) thickness of films, and (c) parameter confidence limits and correlation coefficients. Moreover, the analytical expressions allow researchers to perform simulations of the optical response of an heterostructure or optoelectronic devices, such as

solar cells. In this application, the device designer with a commercial or home-made software should specify the analytical model and its input parameters to calculate the optical functions of each layer material component, which in turn are applied in multilayer optical simulations to predict the transmittance (if any), reflectance, absorbance, and optical quantum efficiency spectra for the specific device.

Fig. 4 shows a pictorial sketch of the ε_1 and ε_2 spectra of crystalline GaAs as a function of photon energy from the far infrared to the vacuum ultraviolet (Blakemore, 1982). These trends are typical for heteropolar semiconductors (III–V, II–VI and their mixed compounds) with crystal structure of diamond or zincblende and for insulators. The strong optical structures around 0.03 eV (the so called reststrahlen region) are due to resonant excitation of transverse lattice vibrational modes of crystal (phonons) promoting absorption of the incident radiation: this absorption is high for semiconductors with ionic component of atom bonding (e.g. Ga^+ and As^-) and weak or absent for purely covalent bonding in homopolar Si and Ge (Yu and Cardona, 1996).

Below the reststrahlen range ε_1 asymptotically approaches the static dielectric constant ε_s , while ε_2 becomes negligibly small. Above the reststrahlen there is a large energy interval where ε_1 and ε_2 are quasi constant, up to ~ 1.4 eV, corresponding to the energy gap E_g of GaAs, where the absorption increases abruptly (fundamental absorption edge). From that energy on, the behavior is due to the electronic interband transitions, that is each electron should be promoted from an occupied valence band state to empty conduction band state through absorption of one incident photon. The sharp structures in ε_2 correspond to the main critical points in the electronic band structure of the crystal (Bassani and Pastori Parravicini, 1974).

These typical dielectric function trends could be importantly influenced by the actual sample material conditions, i.e. free carrier concentration, crystalline phases, and sample temperature of operation, just to cite a few of them.

In the first case the phonon resonances can be screened by increasingly high free-carrier concentration in metals and semiconductors. The so called doping of semiconductors mainly affects the optical response at and below the reststrahlen region, as it is evident in Fig. 5, that reproduces the reflectivity (R) spectrum of bulk GaAs as a function of free electron concentration for n -doping. The strong resonant structure due to the transverse optical phonon is screened progressively with increasing doping; in additional lower photon energies a large plateau with high R values is growing and enlarging, quasi reaching the Dingle plateau (R about unity) typical of metals.

Optical spectra of materials strongly depend also on the order/disorder amount in their crystalline structure. As it is evident for the case of Silicon (Fig. 6), a semiconductor substantially changes in optical response from the monocrystal (prefix: c) to the micro/nano-crystalline ($\mu c - nc$) or amorphous phase (a). The strong and sharp dispersion and absorption peaks of c -Si smear out and reduce to an unique large structure in a -Si. Moreover an elemental or compound material should crystallize in different structures (allotropy), characterized by completely different physical properties, such as the optical functions. A striking and well known example is given by Carbon: it is an insulator within the diamond structure, a semimetal with hexagonal layered structure (graphite), a semiconductor with fullerene structure, an amorphous material with carbon black.

Among the external perturbations which affect the optical properties of solids, material temperature is certainly the most important, both from the fundamental and application point of view. As an example, in Fig. 7 the absorption coefficient of Silicon at the fundamental indirect edge at different temperatures is shown. The two segments of a straight line drawn through the experimental points represent the two contributions due to phonon absorption and emission (see below) (Yu and Cardona, 1996).

Theoretical models

The most important feature characterizing semiconductors and insulators is the energy gap value E_g , which is given by the difference between the minimum energy E_c in the conduction band and the maximum energy E_v of the valence band. The energy E of an electronic state in a band diagram is a function of the electron wavevector k , and if the minimum and the maximum have the

same k , the gap is called direct, otherwise it is called indirect. Most semiconductors and insulators have a direct energy gap, but several technologically important semiconductors such as Si, Ge and GaP have an indirect gap, which limits their use in light emitting devices (LED and lasers).

A simple quantum model (Bassani and Pastori Parravicini, 1974; Yu and Cardona, 1996) for a direct optical transitions at the fundamental absorption edge gives in the parabolic band approximation the following α dependence:

$$\begin{aligned} \alpha &\propto (h\nu - E_g)^{1/2} \text{ for } h\nu \geq E_g \\ \alpha &= 0 \text{ for } h\nu < E_g \end{aligned} \quad (47)$$

Then a plot of the square absorption coefficient α as a function of $h\nu$ should be a straight line, whose intercept with the abscissa gives E_g . In the case the gap is indirect, the momentum conservation in the interband optical transition involves the assistance of a phonon of energy E_p , which can be absorbed or emitted (this last only feasible at $T > 0$). The resulting α dependence in the indirect case is:

Fig. 7 Square root of the absorption coefficients of Si vs photon energy at different temperatures. From Yu PY and Cardona M (1996) *Fundamentals of Semiconductors*. Berlin: Springer-Verlag.

$$\alpha \propto (h\nu \mp E_p - E_g)^2 \text{ for } h\nu \geq E_g \pm E_p \quad (48)$$

$$\alpha = 0 \text{ otherwise,}$$

where + sign refers to one phonon absorption and – sign to emission. We note that the different shape of absorption spectrum makes the experimental distinction between a direct and indirect gap relatively straightforward. Moreover the indirect gap is more sensitive to material temperature, as due to the temperature dependent population of phonons which mediate the optical transitions. In Fig. 7 the two segments of a straight line drawn through the experimental points represent the two contributions due to phonon absorption and emission in accordance with Eq. (48).

Noticeably, Eq. (47) is deduced for perfectly crystalline semiconductors and insulators. Actually, for the majority of samples, dopant impurities, defect levels and other imperfections introduce structural disorder, which is maximum in amorphous materials. Disorder leads to additional energy level tails in valence and conduction bands so that fundamental absorption edge is no more a sharp transition; moreover broad bands of defect levels form in the gap, through which hopping conduction may occur (Adachi, 1999). As a consequence, the absorption coefficient α under the gap E_g shows a near universal exponential tail (the so called Urbach tail) (Urbach, 1953):

$$\alpha(E) = \alpha_0 \exp [(E - E_0)/E_u] \quad (49)$$

where E is the photon energy, E_0 is an energy close to E_g and E_u determines the spectral width of the tail. Above the band edge Tauc and co-workers (Tauc et al., 1966) published for the absorption coefficient the following expression:

$$\alpha(E) = A_T (E - E_g)^2 / E \quad (50)$$

where A_T value and the optical gap energy E_g should be determined by a fit to experimental spectra.

Later on, several models have been proposed, which are extensions of the Urbach and Tauc ones (someone including also Lorentz model), to obtain better fits to experimental spectra above and under E_g , without discontinuities, and to ensure the Kramers-Kronig consistency of ϵ_1 and ϵ_2 (see the reviews of Adachi, 1999, Rodriguez-DeMarcos and Larruquert, 2016).

The optical structures due to interband transitions, lattice vibrations and free-carrier absorption are well fitted by the phenomenological models due to Lorentz and Drude, that highlight the relevant optical fingerprints, allowing an initial feeling for optical properties (Christy, 1972; Wooten, 1972). Moreover, these classical models have quantum mechanical counterparts which are easily understood as generalization of their classical analogs.

The Lorentz model (also called Harmonic Oscillator Approximation, HOA) describes the motion of elementary bound charges in presence of an external electromagnetic field oscillating with frequency ω ; the motion is analogue to a damped harmonic oscillator subject to a periodic external force. The stationary solution for the charge displacement $\mathbf{r}$ is:

$$\tilde{\mathbf{r}} = \frac{q \tilde{\mathbf{E}}_{loc}}{m} \frac{1}{(\omega_0^2 - \omega^2) - i \Gamma \omega} \quad (51)$$

where: q is the charge and m the mass of the oscillator bound by an elastic restoring force $m \omega_0 \mathbf{r}$; ω_0 is the frequency of energy resonance for the oscillator, Γ the coefficient of viscous damping (radiation damping, scattering in a solid); $\mathbf{E}_{loc}$ the local electric field.

For N electrons per unit volume elastically bound to the nucleus with resonance frequency ω_0 , from (51) the dipole moment $\mathbf{p} = -e\mathbf{r}$ follows, then the polarization $\mathbf{P}$ and finally the relative complex dielectric function $\tilde{\epsilon}_r$ (cfr. Eqs. (4), (5) and (10)), with the following expression:

$$\tilde{\epsilon}_r = 1 + \frac{N e^2}{\epsilon_0 m} \frac{1}{(\omega_0^2 - \omega^2) - i \Gamma \omega} \quad (52)$$

Separating the real ϵ_{r1} and the imaginary ϵ_{r2} parts of $\tilde{\epsilon}_r$ we have:

$$\begin{aligned} \epsilon_{r1} = n^2 - k^2 &= 1 + \frac{N e^2}{\epsilon_0 m} \frac{(\omega_0^2 - \omega^2)}{(\omega_0^2 - \omega^2)^2 + \Gamma^2 \omega^2} \\ \epsilon_{r2} = 2nk &= 1 + \frac{N e^2}{\epsilon_0 m} \frac{\Gamma \omega}{(\omega_0^2 - \omega^2)^2 + \Gamma^2 \omega^2} \end{aligned} \quad (53)$$

The frequency dependence of ϵ_{r1} and ϵ_{r2} at each energy resonance is illustrated in Fig. 8: the shape of ϵ_{r1} is termed dispersive, whereas that of ϵ_{r2} , typical of an absorption structure, is called Lorentzian curve. We note that Eq. (52) automatically meets causality, linearity and Kramers- Kronig requirements.

In this classical oscillator model if the considered atom has different types of bound electrons, each with a resonance frequency ω_j , broadening Γ_j and density N_j , as due to additive property of dielectric functions (whereas n and k are not), Eq. (52) should be extended giving:

$$\tilde{\epsilon}_r = 1 + \frac{e^2}{\epsilon_0 m} \sum_j \frac{N_j}{(\omega_j^2 - \omega^2) - i \Gamma_j \omega} \quad \text{with } \sum N_j = N \quad (54)$$

as an example, the ϵ_{r1} and ϵ_{r2} experimental spectra of GaAs are well fitted with 7 Lorentz oscillators as shown in Fig. 9. We underline that these oscillators have no physical origin, i.e. the parameters ω_j of the fit do not necessarily correspond to frequencies of real interband optical transitions.

Fig. 8 Typical spectra of ϵ_{r1} and ϵ_{r2} obtained by the harmonic oscillator model with charge $-e$, resonance frequency $\omega_0 = 4$ eV, damping $\Gamma = 1$ eV. In the region I, II, III and IV the material is primarily transmitting, absorbing, reflecting and transmitting, respectively. From Wooten F (1972) *Optical Properties of Solids*. New York: Academic Press.

Fig. 9 Fit results of harmonic oscillator approximation (HOA) to the experimental ϵ_{r2} spectrum (dots) of GaAs. Individual contribution to ϵ_{r2} of four harmonic oscillators are shown by light solid lines. A better result for seven oscillators is plotted by dashed line. From Adachi S (1999) *Optical Properties of Crystalline and Amorphous Semiconductors*. Boston: Kluwer Academic Publications.

The Lorentz model perform a best-fit also to the lineshape of the absorption and reflectance spectra of infrared active optical phonons, since phonons are quantized simple harmonic oscillators. Then in Eq. (51) q and m are charge and reduced mass of the oscillating ions and $\omega_0 \equiv \omega_T$ is its resonance frequency (T stays for transverse vibration). In Yu and Cardona (1996) several experimental phonon reflectivity spectra of zinc-blende-type semiconductors are reported: they all should be fitted reasonably well with Eq. (51) and the values of the only adjustable parameters ω_0 and Γ are there listed.

A more realistic model for the dielectric function $\tilde{\epsilon}(\omega)$ in the interband region is based on a quantum approach giving a sum (on a continuous background) of lineshape functions, opportunely weighted and centered at the energy of the critical points (CP) in the electronic band structure (Bassani and Pastori Parravicini, 1974, Wooten, 1972). The resulting $\tilde{\epsilon}(\omega)$ expression is:

$$\tilde{\epsilon}_r = 1 + \frac{e^2}{\epsilon_0 m} \sum_j \frac{N f_j}{(\omega_j^2 - \omega^2) - i\Gamma_j \omega} \quad (55)$$

which is formally similar to Eq. (54), but some terms have quite different meaning. In Eq. (55) ω_j is the transition frequency of an electron between two quantum states (respectively in valence and in conduction band), separated by an energy gap of $\hbar\omega_j$. The parameter f_j , called oscillator strength, is the probability of the transition, subjected to the condition $\sum f_j = 1$, which corresponds to the sum rule $\sum N_j = N$ in Eq. (54).

Moreover, the free-carrier optical contribution in doped semiconductors and metals is well reproduced by the Drude model (Christy, 1972; Wooten, 1972), that can be directly derived by Lorentz model nulling the elastic restoring force, that is setting $\omega_0 = 0$ in Eq. (52). In this case the factor $Ne^2/\epsilon_0 m$ coincides with ω_p^2 , where ω_p is the so-called optical plasma frequency of quasi-free electrons, and $\Gamma = 1/\tau$, where τ is the mean free time between collisions. For photon energies $\hbar\omega$ small compared with $k_B T$ (k_B Boltzmann constant and T the absolute temperature) the Drude formulation coincides with quantum result for intraband transitions. As an example, the reflectivity spectra in Fig. 5 were reproduced with Drude-Lorentz models, using parameter values determined by best-fit to experimental spectra.

Finally, the refractive index n values, their dispersion and temperature dependence in the transparency ($k \approx 0$) spectral interval between the fundamental absorption edge and phonon absorption are basic parameters of semiconductors and insulators. They are useful for a lot of applications in optical instruments (e.g. optical crystals and glasses) and photonic devices for multimedia communication systems (optical fibers, focusing, coupling, and modulation of radiation). In Fig. 10 several spectra of refractive index dispersions vs wavelength for various semiconductors and insulators are collected. A few empirical formulae are currently used to simulate the refractive index dispersion, but the most accurate to fit the experimental data, is the following two-pole Sellmeier dispersion model:

$$n^2 = A + \frac{B \lambda^2}{(\lambda^2 - C)} + \frac{D \lambda^2}{(\lambda^2 - E)} \quad (56)$$

where λ is the radiation wavelength (Ghosh, 1998). The term A represents the contribution of the optical transitions at the gaps higher than $E_{g'}$, whereas the second term represents the contribute at $E_{g'}$; the last term, accounting for decrease of n at higher wavelengths, is due to lattice absorption. The values of the coefficients A, B, C, D and E , deduced by best-fit to experimental data of Fig. 10 are also reported. Note that the Sellmeier dispersion model is not Kramers-Kronig consistent, thus is to be considered a valid approximation only on a restrict spectral interval.

Fig. 10 Refractive index spectra vs wavelength for several optical materials in the transparency region between the fundamental absorption edge and the reststrahlen region. From Ghosh G (1998) *Handbook of Thermo-Optic Coefficients of Optical Materials With Applications*. New York: Academic Press. Chapter 2.

Conclusion

In the framework of classical physics, the fundamental quantity describing the optical properties of materials, that is the complex dielectric function $\tilde{\epsilon}$, has been introduced and discussed. The treatment has been limited to the linear response and to homogenous, isotropic, non-magnetic materials. Then the macroscopic quantities related to $\tilde{\epsilon}$, such as the complex refractive index, reflectance, transmittance, absorption, have been introduced. Particular emphasis has been given to the reflection of polarized light and ellipsometry, which is the experimental technique allowing to directly measure both the real ϵ_1 (dispersive) and the imaginary ϵ_2 (dissipative) parts of $\tilde{\epsilon}$.

A few experimental optical spectra are reported, which are selected to describe the main features of the optical response of solids from the far-infrared to vacuum ultraviolet, with their dependence on crystalline order, doping and temperature. Moreover, simple theoretical models, both phenomenological and derived from quantum treatments, with the analytical expressions for the optical functions are recalled. Their best-fits to experimental data allow the determination of some fundamental parameters which, in the usual theory-experiment feedback loop, enable to refine the calculated electronic and vibrational structures, and to simulate and design multilayered photonic devices.

During the last 40 years the impressive progress in epitaxial techniques allowed to growth micro/nano-structures and related devices exhibiting new optical features which extend and deepen the understanding of the optical properties of materials, while substantially respecting the above considerations. A more recent striking case is represented by optical metamaterials, designed to obtain artificial structures with properties not found in nature. Their unique optical properties, such as negative refractive index (which do not break the laws of physics), can be extended from GHz all the way to optical frequencies. After 20 years of research, today the metamaterials move out of the lab, promising enhanced performance in applications, from optical accessories to photonics devices.

Abstract

The statistical properties of light are discussed in the classical and quantum optics context, looking at the different features of the two approaches. Optical fluctuations are characterized according to the three statistical distributions in which they can occur, Poissonian, super Poissonian and sub Poissonian, respectively. The corresponding behaviors are discussed by studying first the expressions of the variances, then by looking at the respective correlation functions and coherence degrees, at the first and second order. This leads to demonstrate that only an analysis performed at the second order degree of coherence allows to distinguish among the three statistical behaviors and between classical and nonclassical light. The study of the peculiar properties of nonclassical light allows also to discuss the role played by photodetector efficiency within the different photon statistics. According to the values of the degree of second order coherence, a further way to identify the behavior of light, namely coherent, bunched and antibunched, is introduced. Finally, the peculiar role played by the beam splitter on the output state statistics, for some experimental condition, is discussed.

Key points

Introduction

The study of optical fluctuations gives us the possibility to understand the statistical properties of light. There are different kinds of light, each one characterized by a particular statistical distribution (Mandel and Wolf, 1965). Depending on the size of fluctuations, three different photon statistics can be considered, namely *Poissonian*, *super-Poissonian* and *sub-Poissonian*. We will describe the main characteristics of these kinds of light in Sections “Coherent light – Poissonian statistics,” “Thermal and chaotic light – Super Poissonian statistics,” “Nonclassical light – Sub Poissonian statistics and role of quantum detection efficiency,” where the main properties of the corresponding photon statistical distribution are discussed.

A deep knowledge of the different kinds of light cannot be separated from the role played by *photodetection*. This aspect will be briefly examined in paragraph 3 regarding its consequences on quantum light detection.

The statistical properties of Poissonian, super-Poissonian and sub-Poissonian light is studied by performing *correlation measurements* between different parts of the *light beam*, each one associated to a particular set of space-time coordinates. By *first-order*

[☆]Change History: July 2022. P. Mataloni updated the chapter.

correlation measurements it is not possible to distinguish between the various photon statistics, an objective that can be achieved by performing *second-order* correlation measurements, e.g. by measuring *intensity/photon* correlations. We will first discuss this aspect in Section “*First order coherence*” by examining first-order coherence phenomena.

Depending on its nature, light can show either *classical* or *nonclassical* behaviors. While the Poissonian and super Poissonian light properties are described in an equivalent way either in the classical or in the *quantum* frame, the peculiar features of sub Poissonian light can be explained only by a fully quantum approach. Indeed, it is only through second-order correlation measurements that it is possible to distinguish between classical and nonclassical behaviors, as said. Second-order coherence degree will be introduced in Sections “*Second order coherence*” and, “*Brown-Twiss correlations – Photon bunching and photon antibunching*” for the three models of photon statistics, using either a classical or a quantum description and it will be used also to describe the phenomena of *photon bunching* and *antibunching*. Section “*Basic photon statistics at beam splitters*” describes the consequences on photon statistics related to a few physical situations in which single and two photon states impinge on a beam splitter.

Coherent light – Poissonian statistics

It is well known that the intimate nature of optical phenomena can be explained by considering light not only in terms of waves but also of particles. Referring to these concepts the theoretical study of optical phenomena has developed over the years following both classical and quantum theory. Among the various characteristics of light, a full comprehension of its statistical properties can be achieved by considering light as a photon stream rather than as an electromagnetic wave. It is in particular this granular picture that allows us to justify the unavoidable presence of optical fluctuations both in the classical and quantum approach.

To understand the statistical phenomena of a photonic stream we need to consider that a photon counting measurement is affected not only by the intrinsic instabilities of the light beam but also by those typical of a photon counter, deriving from the non-perfect quantum efficiency of detector. We may disregard this effect for the moment by implicitly assuming a 100% photo-detector quantum efficiency.

To have an idea of the photon fluctuations associated to a photonic stream, let's consider the model of a continuous wave (cw) single-mode laser beam operating above threshold, a situation implying a stable output power. This kind of light represents the best approximation of a classical monochromatic beam, perfectly coherent, since amplitude, frequency and phase are constant.

The number of photons per second of a laser is extremely high, even in the case of a low output power. Nearly 3×10^{15} photons/sec are generated by a Helium-Neon (He—Ne) laser with an output power of 1 mW, hence, in the example we are going to discuss, it's more simple to consider a laser beam attenuated of at least a factor 10^6 .

By dividing the light beam into gradually shorter temporal segments and sampling photons in each of them, statistical fluctuations become more and more evident because of the random temporal distribution of photons. At a certain point, for short enough time intervals, the main part of them will be empty while the segments containing one photon become rare and with a negligible number of segments containing two or more photons. This feature is peculiar of a Poissonian photon distribution. This can be demonstrated by considering a beam of finite length containing an average number of photons $\bar{n}$ and divided in N equal subsegments. It comes out that the probability of finding n subsegments with one photon and $(N - n)$ with zero photons, equivalent to the probability of counting n photons in the beam, is given by the binomial distribution: $P(n) = \frac{N!}{n!(N-n)!} p^n (1-p)^{N-n}$, where $p = \frac{\bar{n}}{N}$. It is possible to demonstrate that, in the limit $N \rightarrow \infty$, this probability corresponds exactly to the Poisson distribution:

$$P(n) = \frac{\bar{n}^n}{n!} e^{-\bar{n}} \quad (n = 0, 1, 2, \dots) \quad (1)$$

whose characteristic parameters are the mean value:

$$\bar{n} \equiv \langle n \rangle = \sum_{n=0}^{\infty} n P(n) \quad (2)$$

and the variance:

$$\text{Var}(n) \equiv (\Delta n)^2 = \sum_{n=0}^{\infty} (n - \bar{n})^2 P(n) = \bar{n} \quad (3)$$

the second one indicating the amount of spread of the distribution.

The standard deviation of the photon counting measurements is, accordingly, $\Delta n = \sqrt{\bar{n}}$ and the fractional uncertainty in the number of photons of the coherent beam is expressed as:

$$\frac{\Delta n}{\bar{n}} = \frac{1}{\sqrt{\bar{n}}} \quad (4)$$

with $\frac{\Delta n}{\bar{n}} \rightarrow 0$ for increasing $\bar{n}$. This result approaches the behavior of a classical wave for a large photon number.

The Poisson distribution applies to a coherent cw laser beam which is, as said, the best approximation of a classical stable wave, with the relevant difference that, in the case of a classical wave, the variance, expressed in terms of the intensity, vanishes: $(\Delta I)^2 = 0$.

The nonvanishing value of Δn is the consequence of the particle-like nature of light in the quantum approach. According to (4) this aspect becomes less and less relevant with increasing $\bar{n}$, a condition in which the Poisson distribution approaches a Gaussian distribution.

We may adopt the Poissonian coherent light as a term of comparison with other kinds of light, considering for each of them the variance of the corresponding statistical distribution.

Thermal and chaotic light – Super Poissonian statistics

To understand the typical features of super-Poissonian statistics we refer to the case of *thermal light*, the radiation emitted by an ideal object known as a black body, a perfect emitter and absorber of radiation. A black body can be modeled as a cavity containing radiation at thermal equilibrium with its walls. Within the continuum spectrum of modes oscillating in the cavity we consider a single mode field with quantized energy $E_n = (n + \frac{1}{2})\hbar\omega$. A good example of thermal light source is given by a filament lamp, where photon number fluctuations derive from the random presence of the absorption and emission processes occurring therein with a characteristic time depending on the operation parameters of the source, such as the temperature.

According to statistical mechanics the probability that the mode is thermally excited to its n th excited state, a situation corresponding to having n photons in the mode, is given by the Boltzmann factor:

$$P(n) = \frac{\exp(-n\hbar\omega/k_B T)}{\sum_n \exp(-n\hbar\omega/k_B T)}, \text{ where } k_B \text{ is the Boltzmann constant.}$$

Adopting the notation $x = \exp(-\hbar\omega/k_B T)$ the thermal probability is expressed as

$$P(n) = \frac{x^n}{\sum_{n=0}^{\infty} x^n} \quad (5)$$

and the average number of photons excited in the mode at temperature T is:

$$\bar{n} = \sum_n nP(n) = \frac{x}{1-x} = \frac{1}{\exp(\hbar\omega/k_B T) - 1} \quad (6)$$

Starting from (5), we define $x = \frac{\bar{n}}{(1 + \bar{n})}$ and arrive to an alternative expression of the probability given in (2.1), namely the *Bose-Einstein distribution*,

$$P(n) = \frac{\bar{n}^n}{(1 + \bar{n})^{1+n}} \quad (7)$$

It is significantly broader than the Poissonian distribution for any value of $\bar{n}$, as shown in Fig. 1. A coherent and a thermal source having the same average number $\bar{n}$ of photons, the same frequency and bandwidth, are expected to have completely different photon statistics because of their different photon distributions.

An indication of the size of fluctuations related to the number of photons is given by the variance, expressed as: $(\Delta n)^2 = \sum_{n=0}^{\infty} (n - \bar{n})^2 P(n) = \bar{n}^2 + \bar{n}$. It is possible to demonstrate that in the case of a thermal distribution the variance is given by the sum of two contributions, related respectively to the wave-like and the particle-like nature of the photon:

$$(\Delta n)^2 = \bar{n}^2 + \bar{n} > \bar{n} \quad (8)$$

Fig. 1 Poisson and Bose-Einstein distributions ($\bar{n} = 10$).

This result gives direct evidence of the super-Poissonian nature of thermal light. Regarding the standard deviation, $\Delta n \rightarrow \bar{n}$ for $\bar{n} \gg 1$, moreover the fractional uncertainty in the number of photons, $\frac{\Delta n}{\bar{n}} = \sqrt{1 + \frac{1}{\bar{n}}} \rightarrow 1$ for increasing $\bar{n}$. Compared with the fractional uncertainty of a Poissonian light, these results clearly demonstrate the different behavior of super Poissonian light for many photons.

Chaotic light, produced by a common spectroscopic source, such as a gas discharge lamp, is a further example of super Poissonian light. The gas atoms present in the source are randomly excited by an electrical discharge and emit radiation on a single spectral line independently of one another.

The behavior of chaotic light can be investigated by looking at the time dependence of the amplitude or intensity of the light beam. It is known from spectroscopy that line broadening processes present in a source are responsible of the intensity fluctuations occurring around an average value on a timescale which is inversely proportional to the bandwidth of the spectrum. The temporal fluctuations and the frequency spectrum of light are complementary manifestations of the same physical properties of the light source. In the present case, the superposition of the emission of many independent atoms radiating with different phases and frequencies, is precisely responsible for the generation of the chaotic light.

We consider the classical model of a N -excited-atom source with emission linewidth broadened by collisions occurring at a rate $\gamma_{\text{coll}}[\text{sec}^{-1}]$, e.g. with a coherence time $\tau_c = 1/\gamma_{\text{coll}}$. An example of the wave trains radiated by a single atom after each collision is shown in Fig. 2, where the electric field amplitude is schematically represented as a function of time.

The total electric field radiated by N identical atoms is expressed as:

$$E(t) = \sum E_i(t) = E_0 \exp(-i\omega_0 t) [\exp(i\varphi_1(t)) + \exp(i\varphi_2(t)) + \dots + \exp(i\varphi_N(t))] \quad (9)$$

where E_0 and ω_0 are the amplitude and the frequency of the field radiated by a single atom. Similarly, $\varphi_i(t)$, for $i = (1, 2, \dots, N)$, corresponds to the random phase associated to the wave emitted by each atom. The average frequency spectrum (in the present case atom collisions determine a Lorentzian spectrum centered at ω_0) is obtained by the Fourier decomposition of $E(t)$. It is worth noting that collisions are not the only effect responsible of line broadening. A further mechanism is given by the Doppler effect which determines a Gaussian frequency broadening.

The beam intensity is proportional to $|E(t)|^2$. It is a random function of time, varying on a timescale of the order of the coherence time τ_c . The cycle-averaged intensity $I(t)$ is defined as the average of the intensity over an oscillation cycle at frequency ω_0 . In many cases the corresponding fluctuations are too rapid to be detected, so that one can measure the average of the fluctuations over the response time of the detector. Fig. 3 shows the computer simulation of a typical temporal evolution of the cycle-averaged intensity for a chaotic light beam.

The average intensity $\bar{I}$ is the result of the ensemble average over many values of $I(t)$, measured over a period much longer than τ_c :

Fig. 2 Sequence of wave trains emitted for chaotic light.

Fig. 3 Temporal evolution of chaotic light.

$$\bar{I} = \overline{I(t)} \propto \overline{|E(t)|^2} = E_0^2 \overline{|\exp(i\varphi_1(t)) + \dots + \exp(i\varphi_N(t))|^2} = NE_0^2 \quad (10)$$

This result is a consequence of the zero average contribution of the cross-terms between the phase factors of different radiating atoms. The dashed line in Fig. 3 indicates the value of $\bar{I}$ corresponding to the fluctuating intensity.

We can calculate the mean value of $I(t)^2$ by the same procedure:

$$\overline{I(t)^2} \propto E_0^4 \overline{|\exp(i\varphi_1(t)) + \dots + \exp(i\varphi_N(t))|^4} = E_0^4 [N + 2N(N-1)] = \left(2 - \frac{1}{N}\right) \bar{I}^2 \quad (11)$$

Since the number N is very large ($N \gg 1$), we obtain: $\overline{I(t)^2} = 2\bar{I}^2$. It comes out the important result regarding the variance:

$$(\Delta I)^2 = \overline{I(t)^2} - \bar{I}^2 = \bar{I}^2 \quad (12)$$

According to what we have found in the case of thermally excited photons within a single cavity mode for $\bar{n} \gg 1$, the size of fluctuations, given by the standard deviation ΔI , is equal to $\bar{I}$, confirming in this way the super-Poissonian behavior of the chaotic source.

Other examples of (quasi)thermal/(quasi)chaotic light have been studied in the years. As an example, we remember the source realized by passing a single mode cw laser light beam through a rotating ground-glass. The intensity fluctuation properties of this source are similar as the ones of true thermal light except for the large number of photons involved (much larger than 1) and for the coherence time that can be varied between 10^{-5} sec and 1 sec (Martienssen and Spiller, 1964).

A single-mode laser operating below threshold or a multi-mode laser exhibit in suitable conditions the characteristic behavior of a chaotic light.

It is worth underlining that the results described above in the case of chaotic light are valid only if the integration time of the intensity measurement is much shorter than the coherence time. If this is not the case, the measurement corresponds to an average operation performed over more than one fluctuation and the measured statistical behavior appears as a Poissonian one.

Nonclassical light – Sub Poissonian statistics and role of quantum detection efficiency

Entering in the region defined by the relation $\Delta n < \sqrt{n}$ i.e., going below the Poissonian statistics limit, corresponds to enter in the region of nonclassical photon states. Sub Poissonian statistics is indeed one of the signatures of the quantum nature of light.

A pure nonclassical state is given by a *photon number state* $|n\rangle$ ($n = 1, 2, \dots$), provided by a stream of periodically spaced identical photons. The corresponding photon number distribution is:

$$P(n) = \delta(n, \bar{n}) \quad (13)$$

where $\delta = 1$ for $n = \bar{n}$ and $\bar{n}$ is an integer. In this peculiar condition the standard deviation vanishes, $\Delta n = 0$, since the number of photons is perfectly defined. Besides the pure state limit represented by (13), the sub Poissonian requirement $\Delta n < \sqrt{\bar{n}}$ is satisfied even in the case of a non-constant time interval between photons, provided that the photon sequence is not completely random as for Poissonian light.

Quantum light has great importance in modern quantum optics because of its applications whenever transmission of signals through single photons is required, as in quantum communications and quantum computing. One could think to attain the single-photon regime by strongly attenuating a laser beam to ensure that the probability of having more than one photon becomes negligible. It is worth to point out that this method is poorly efficient because of the intrinsic Poissonian statistics that obliges to strongly increase the attenuation of the coherent beam to make negligible the events with 2 or more photons.

Heralded single photon sources based on spontaneous parametric down-conversion (Harris et al., 1967; U'Ren et al., 2005) have been so far widely adopted to generate single photons, however their main limitation resides on the probabilistic nature of the spontaneous emission process. More recently, a new generation of single photon sources, built on single quantum dots excited by a perfect sequence of femtosecond laser pulses and operating within optical microscopic cavities, have been demonstrated to generate single photons at high repetition rate, approaching in this way the model of a single-photon deterministic source (Senellart et al., 2017).

Other approaches to single photon generation have been demonstrated, among the others we remember the possibility of storing excitation in an atomic ensemble falling neutral atoms (Chou et al., 2004) and the use of defects in diamond nanocrystals (Kurtsiefer et al., 2000).

Single photon states are very fragile. Indeed, in the actual experimental conditions sub Poissonian statistics suffers both the optical losses of the experimental setup and the imperfect quantum efficiency of detectors. The two processes determine a random sampling of the photons; therefore, the quantum photon statistics tends to be degraded to the Poissonian one.

We have not considered up to now the quantum efficiency η of the detectors since we implicitly assumed to work with $\eta = 1$. We conclude this section by briefly examining the role played by photodetection statistics when $\eta = \frac{\bar{m}}{\bar{n}} \leq 1$, with $\bar{n}$ and $\bar{m}$ corresponding respectively to the average number of photons and of photoelectrons ejected by the photodetector.

The granular nature of light is also reflected in photon counting in optical devices, causing the presence of the so-called *shot noise* of the electric charges emitted by the detector. Shot noise is also called Poisson noise, since it can be modeled by a Poisson process. According to the semiclassical theory of optical photodetection, it is immediate to see that, in the case of a Poissonian coherent light the photocount statistical distribution is still Poissonian.

A Poissonian photocount distribution holds also for a light beam in which the intensity varies in time such as for chaotic light, provided that the integration time Δt of detection is much longer than the coherence time τ_c of the light. In this case the photocount variance is Poissonian, $(\Delta m)^2 = \bar{m}$. On the other hand, when $\Delta t \ll \tau_c$, the photocount distribution reproduces the one of a super Poissonian light, $(\Delta m)^2 = \bar{m} + \bar{m}^2$.

The semiclassical theory is not adequate to describe quantum light detection, thus a full quantum treatment of photodetection is necessary to understand how a detector operates with sub-Poissonian light and how much it is important to work with high efficiency photodetectors.

According to the quantum treatment of photodetection the relationship existing between $(\Delta m)^2$ and $(\Delta n)^2$ is given by:

$$(\Delta m)^2 = \eta^2 (\Delta n)^2 + \eta(1-\eta)\bar{n} \quad (14)$$

The analysis of (14) suggests the following conclusions:

- 1) For $\eta = 1$ it comes out that $\Delta m = \Delta n$, hence photon fluctuations are automatically transferred to photocount fluctuations.
- 2) In the case of a Poissonian light, $(\Delta n)^2 = \bar{n} \rightarrow (\Delta m)^2 = \eta\bar{n} \equiv \bar{m}$, for any value of η . We have in this case a Poissonian photocount statistics regardless the value of η .
- 3) For $\eta \ll 1 \Rightarrow (\Delta m)^2 = \eta\bar{n} \equiv \bar{m}$, regardless the incoming photon statistics.

We conclude that only a large value of quantum efficiency ($\eta \Rightarrow 1$) guarantees a faithful measurement of a sub-Poissonian photon statistic. An imperfect detector will randomize more and more the photoelectron stream and the measured statistics will fatally become Poissonian.

First order coherence

To deepen our understanding of optical fluctuations we need to introduce the concept of coherence in its various meanings both in classical and quantum optics. On the one hand the concept of coherence has been always associated with interference optical phenomena, on the other hand it is involved in the entire field of statistical optics and, more in general, in the quantum description of photon states. In its broadest sense, optical coherence theory deals with the statistical description of fluctuations, thus it can be said that optical coherence phenomena are manifestations of the correlations existing within them (Mandel and Wolf, 1965).

The first-order correlation function of the electric field at times t and $t + \tau$ is defined as

$$G^{(1)}(\tau) = \overline{E^*(t)E(t+\tau)} \quad (15)$$

It expresses how the value of the electric field at time $t + \tau$ is affected by the value at time t . It comes out that $G^{(1)}(0) = \overline{|E^*(t)E(t)|^2} = \overline{I(t)} = I$ for $\tau = 0$. Furthermore, $G^{(1)}(-\tau) = G^{(1)*}(\tau)$, because of its Hermitian symmetry.

The degree of first-order temporal coherence, defined as

$$g^{(1)}(\tau) = \frac{G^{(1)}(\tau)}{G^{(1)}(0)} = \frac{\overline{E^*(t)E(t+\tau)}}{\overline{E^*(t)E(t)}} \quad (16)$$

is a complex function, independent of the intensity, with the properties: $g^{(1)}(-\tau) = g^{(1)*}(\tau)$ and $0 \leq |g^{(1)}(\tau)| \leq 1$. The value of $|g^{(1)}(\tau)|$ gives us a measure of the amount of correlation existing between $E(t)$ and $E(t + \tau)$.

In the ideal case of a monochromatic plane wave of amplitude E_0 , $E(t) = E_0 \exp(-i\omega_0 t)$ the degree of first-order temporal coherence becomes

$$g^{(1)}(\tau) = \exp(-i\omega_0 \tau) \quad (17)$$

and $|g^{(1)}(\tau)| = 1$, meaning that $E(t)$ and $E(t + \tau)$ are fully correlated whatever the value of τ . In the real case of a single mode coherent laser beam this result can be valid for large values of τ (up to nearly 3 msec for a single mode solid state laser).

For a chaotic collision-broadened light the correlation function of the whole light beam is obtained from the single-atom contribution,

$$\overline{E^*(t)E(t+\tau)} = NE_0^2 \exp\left(-i\omega_0 \tau - \frac{\tau}{\tau_c}\right) \quad (18)$$

Thus, the first-order coherence degree is:

$$g^{(1)}(\tau) = \exp\left(-i\omega_0 \tau - \frac{|\tau|}{\tau_c}\right), \text{ with modulus } |g^{(1)}(\tau)| = \exp\left(-\frac{|\tau|}{\tau_c}\right) \quad (19)$$

Note that the exponential shape of $|g^{(1)}(\tau)|$ is consistent with the characteristic Lorentzian frequency spectrum holding for a line shape broadening due to collisions.

Insofar as other broadening effects are concerned, one can consider the case of chaotic light generated by atoms in a gas characterized by a spread in their velocities. The consequent Doppler broadening effect leads to a Gaussian distribution of the emission frequencies. In this case the degree of first-order coherence is

Fig. 4 Modulus of the first-order coherence degree expressed in function of the normalized time delay τ/τ_c for collision-broadened and Doppler-broadened chaotic light. The red dashed line corresponds to the case of coherent light.

$$g^{(1)}(\tau) = \exp \left[-i\omega_0\tau - \frac{\pi}{2} \left(\frac{\tau}{\tau_c} \right)^2 \right], \text{ with modulus } |g^{(1)}(\tau)| = \exp \left[-\frac{\pi}{2} \left(\frac{\tau}{\tau_c} \right)^2 \right] \quad (20)$$

where $\tau_c = \frac{\sqrt{\pi}}{\Delta}$ and Δ^2 corresponds to the variance of the Gaussian distribution.

Fig. 4 shows how $|g^{(1)}(\tau)|$ varies with τ for a partially coherent light in the two cases of collision and Doppler broadening. The dashed line $|g^{(1)}(\tau)| = 1$ corresponds to the case of a monochromatic coherent wave.

Light emitted from a partially coherent source is modeled as a sequence of random, uncorrelated wave packets, each one with a characteristic longitudinal coherence length $l_c = c\tau_c$. The values of the coherence times and the corresponding values of l_c are shown in Table 1 for different kinds of light sources. The case of a single-mode laser, whose coherence length is of the order of several hundreds of meters, represents the best approximation of a monochromatic plane wave with $l_c = \infty$, as said.

The same formalism adopted for temporal correlation can be used to investigate $g^{(1)}(r_1, r_2)$ in the case of two spatial points of the wavefront with coordinates r_1 and r_2 ,

$$g^{(1)}(r_1, r_2) = \frac{G^{(1)}(r_1, r_2)}{\sqrt{[I(r_1)I(r_2)]}} \quad (21)$$

By this expression, knowing $|g^{(1)}(r_1, r_2)|$ ($0 \leq |g^{(1)}(r_1, r_2)| \leq 1$) it is possible to determine the radius of the transverse coherence area. In the ideal case of a coherent plane wave, $|g^{(1)}(r_1, r_2)| = 1$ whatever the distance $r_1 - r_2$. This is equivalent to say that the coherence area of a plane wave is infinitely large. In the general case, the first order coherence degree $g^{(1)}(r_1, r_2)$ is defined for any pair of space-time points.

The beam splitter (BS) is an essential tool, in classical and quantum optics, for the understanding of interference phenomena and for its profound implications with photon statistics. In the last section an overview on the fundamental role of BS in quantum optics is presented. For the moment it is sufficient to consider the BS as a semitransparent mirror with the following characteristics:

- reflection coefficient $r = |r|e^{i\varphi}$
- transmission coefficient $t = |t|e^{i\theta}$

We will consider in general a symmetric BS, having equal probability to reflect or transmit the light, $R = T = \frac{1}{2}$, being $R = |r|^2$ and $T = |t|^2$ the reflectivity and the transmittivity of the BS.

A Mach-Zehnder interferometer (MZI), composed of two symmetric BSs and two total reflecting mirrors (M), operating at 45 deg., is sketched in Fig. 5.

The light beam is incident on one of the two input ports of the first BS and is divided into two equal beams, with electric field $E_1(t)$ and $E_2(t)$, traveling through the two optical paths 1 and 2. The two beams meet in the second BS, where superposition and interference of the two electric fields occur, depending on the relative phase ϕ .

Table 1 Coherence times and coherence lengths of different light sources.

Source	Coherence time τ_c	Coherence length l_c
White light (400–700 nm)	3.6 fsec	1.08 μm
LED ($\lambda = 800 \text{ nm}$, $\Delta\lambda = 50 \text{ nm}$)	43 fsec	0.01 mm
Spectral lamp (Hg)	10 psec	3 mm
Multimode cw He—Ne laser ($\lambda = 633 \text{ nm}$)	0.67 nsec	20 cm
Single mode Nd: YAG laser ($\lambda = 1064 \text{ nm}$)	3 msec	900 m

Fig. 5 The Mach Zehnder interferometer

By the above assumptions, one has $g_{12}^{(1)} = \frac{E_1^* E_2}{\sqrt{I_1 I_2}}$. The average intensity corresponding to the two-wave superposition is:

$$I = |E_1 + E_2|^2 = I_1 + I_2 + 2\sqrt{I_1 I_2} |g_{12}^{(1)}| \cos \phi \quad (22)$$

Where ϕ is the phase of $g_{12}^{(1)}$. It can be suitably adjusted by varying, within half of the wavelength $\lambda = \frac{2\pi c}{\omega}$, the delay between the two optical paths. Optical interference arises exactly from the third term of the above expression, thus, from the value of the mutual correlation degree, $g_{12}^{(1)}$. Two important cases are considered, depending on the limit values of $g_{12}^{(1)}$:

$$|g_{12}^{(1)}| = 1 \text{ (coherent waves)} \Rightarrow I = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos \phi \quad (23)$$

$$|g_{12}^{(1)}| = 0 \text{ (incoherent waves)} \Rightarrow I = I_1 + I_2 \quad (24)$$

In the general case of partially coherent waves, $0 \leq |g_{12}^{(1)}| \leq 1$, the intensity I is a sinusoidal function of ϕ ; the larger the $|g_{12}^{(1)}|$, the larger the amplitude of the oscillation. In this case, measuring the interference strength as a function of the optical path delay, all the necessary information about the temporal or spatial behavior of the correlation degree, such as the temporal coherence length or the transverse coherence radius of the light beam, are obtained. One can express the modulation depth by the visibility parameter

$$V = \frac{I_M - I_m}{I_M + I_m} = 2 \frac{\sqrt{I_1 I_2}}{I_1 + I_2} |g_{12}^{(1)}| \quad (25)$$

where I_M and I_m are the maximum and the minimum of light intensity corresponding to $\phi = 0$ and $\phi = \pi$, respectively. In a symmetric interferometer ($I_1 = I_2$), $V = |g_{12}^{(1)}|$. For $|g_{12}^{(1)}| = 1$ we have $I_M = 4I$ and $I_m = 0$. It is worth to remember once more that the results given from (22) to (25) holds for both Poissonian and single-mode super Poissonian light. Regarding first-order coherence phenomena, there is no way to distinguish between the different statistical distributions of a single mode laser and a chaotic light source.

The description of first order coherence given so far, based on classical wave theory, allows to explain any kind of interference phenomena. In fact, there is no way to recognize different behaviors between classical and nonclassical light at the level of first-order interference phenomena. In quantum optics, where a single mode quantum photon state is equivalent to a n -level quantum harmonic oscillator, the general expression of a single mode scalar electric field operator is:

$$\hat{E}(\chi) = \hat{E}^+(\chi) + \hat{E}^-(\chi) = \frac{1}{2} \hat{a} e^{-i\chi} + \frac{1}{2} \hat{a}^\dagger e^{i\chi} \quad (26)$$

where $\hat{E}^+(\chi)$ and $\hat{E}^-(\chi)$ are the positive and negative frequency parts of the electric field operator and $\chi = \omega_0 t - k z - \frac{\pi}{2}$ corresponds to the phase angle of the optical field propagating with wavevector k along the direction z . In (26) $\hat{a}^\dagger$ and $\hat{a}$ are the creation and destruction operators for the harmonic oscillator. Writing the expression of the first order correlation function for two fields $\hat{E}(\chi_1)$ and $\hat{E}(\chi_2)$, having different phase angles, e.g. with $|\chi_1 - \chi_2| = \omega_0 \tau$, it is immediate to verify that $g^{(1)}(\chi_1; \chi_2) = g^{(1)}(\tau) = \exp(i\omega_0 \tau)$ (Glauber, 1963).

These simple passages demonstrate that the quantum description of first order coherence returns the same results obtained by classical theory, therefore no difference exists between classical and quantum predictions at the level of first order interference phenomena.

In the next paragraph, we will see that this is possible within the context of second order coherence.

Second order coherence

As done for first-order coherence, consider two temporal measurements in which many pairs of samples of the cycle-averaged intensity are measured at a fixed delay τ . The classical definition of the intensity correlation function, valid either for chaotic or coherent light, corresponds to the average of the products of each pair of samples:

$$G^{(2)}(\tau) = \overline{I(t)I(t+\tau)} = \overline{E^*(t)E^*(t+\tau)E(t+\tau)E(t)} \quad (27)$$

The correlation function $G^{(2)}(\tau)$ can be normalized to the square of the long-time-averaged intensity $\overline{I(t)}$ given in (10) to obtain the degree of second-order temporal coherence:

$$g^{(2)}(\tau) = \frac{\overline{I(t)I(t+\tau)}}{\overline{I(t)}^2} = \frac{\overline{E^*(t)E^*(t+\tau)E(t+\tau)E(t)}}{\overline{E^*(t)E(t)}^2} \quad (28)$$

Because of symmetry properties, $g^{(2)}(\tau) = g^{(2)}(-\tau)$. Furthermore, the following inequalities can be demonstrated:

$$1 \leq g^{(2)}(0) \leq \infty \leq g^{(2)}(\tau) \leq \infty g^{(2)}(\tau) \leq g^{(2)}(0) \quad (29)$$

For a large number N of radiating atoms, it is possible to obtain $g^{(2)}(\tau) = 1 + |g^{(1)}(\tau)|^2$. Thus, in the two cases of collision and Doppler broadening, we can write, respectively:

Fig. 6 Second-order coherence degree expressed in function of the normalized time delay τ/τ_c for collision-broadened and Doppler-broadened chaotic light. The red dashed line corresponds to the case of coherent light.

$$g^{(2)}(\tau) = 1 + \exp\left(-2\frac{|\tau|}{\tau_c}\right) \quad g^{(2)}(\tau) = 1 + \exp\left[-2\pi\left(\frac{\tau}{\tau_c}\right)^2\right] \quad (30)$$

It comes out that, for both cases, $g^{(2)}(0) = 2$ and $g^{(2)}(\tau \gg \tau_c) = 1$.

Fig. 6 shows the behavior of $g^{(2)}(\tau)$ of both the models of chaotic light having Lorentzian and Gaussian frequency distribution. Starting from $g^{(2)}(0) = 2$ at zero-time delay, the intensities $I(t)$ and $I(t + \tau)$ become more and more uncorrelated by increasing τ , therefore $g^{(2)}(\tau) \rightarrow 1$. At variance with chaotic light, for a classical stable wave, $g^{(2)}(\tau) = 1$ for any value of τ . This case is represented by the horizontal dashed line in the same Figure (Arecchi, 1965).

Similarly with the case of first-order coherence, the definition of the second-order coherence degree can be generalized to the spatial case,

$$g^{(2)}(\mathbf{r}_1, \mathbf{r}_2) = \frac{E^*(\mathbf{r}_1)E^*(\mathbf{r}_2)E(\mathbf{r}_2)E(\mathbf{r}_1)}{|E(\mathbf{r}_1)|^2|E(\mathbf{r}_2)|^2} \quad (31)$$

and more in general, $g^{(2)}(\mathbf{r}_1, t_1; \mathbf{r}_2, t_2)$ can be defined for any pair of space-time points.

One of the main features of the degree of second-order coherence measurement consists of the possibility of distinguishing between classical and nonclassical radiation. So far, the main aspects of optical coherence have been analyzed in terms of the classical wave theory of light. The particle aspect of light is considered whenever it is possible to count photons (or rather, the photoelectrons ejected from a photoemissive surface by the absorption of photons).

Let's consider a single mode nonclassical photon state $|n\rangle$, equivalent to a n -level quantum harmonic oscillator. For the creation and destruction operators $\hat{a}^\dagger$ and $\hat{a}$ the following equations hold:

$$\hat{a}^\dagger |n\rangle = \sqrt{n+1} |n+1\rangle \quad \hat{a} |n\rangle = \sqrt{n} |n-1\rangle \quad (32)$$

where n is the number of photons belonging to the state $|n\rangle$ with $\hat{n}|n\rangle = n|n\rangle$. According to the expression of a single mode electric field given in (26), we can express the mutual degree of second order coherence of two fields, $\hat{E}(\chi_1)$ and $\hat{E}(\chi_2)$ in terms of the operators $\hat{a}^\dagger$ and $\hat{a}$

$$g^{(2)}(\tau) = g^{(2)}(\chi_1; \chi_2) = \frac{\overline{\hat{a}^\dagger \hat{a}^\dagger \hat{a} \hat{a}}}{\overline{\hat{a}^\dagger \hat{a}}^2} \quad (33)$$

It is worth noting that, similarly with the first order coherence function, the expression of $g^{(2)}(\tau)$ doesn't depend on the spatial and temporal coordinates. On the other hand, we have seen for classical light that, at variance with $g^{(1)}(\tau)$, $g^{(2)}(\tau)$ is strictly dependent on the nature of light. With $\hat{a}^\dagger \hat{a} = \hat{n}$ corresponding to the photon number operator and considering that the commutator of the creation and destruction operators is $[\hat{a}, \hat{a}^\dagger] = \hat{a}\hat{a}^\dagger - \hat{a}^\dagger \hat{a} = 1$, we are able to obtain a new expression of $g^{(2)}(\tau)$ in terms of the average and average square number of photons of the field:

$$g^{(2)}(\tau) = \frac{\overline{n(n-1)}}{\bar{n}^2} = \frac{\bar{n}^2 - \bar{n}}{\bar{n}^2} \quad (34)$$

This expression of $g^{(2)}(\tau)$ can be explained as follows: the probability of counting a photon is proportional to the number of photons n in the field. Since the number of photons available in a second measurement is reduced by one unit, the probability of counting a second photon is proportional to $n-1$, therefore the two-photon counting probability is proportional to $\overline{n(n-1)} = \bar{n}^2 - \bar{n}$. Note that this expression of $g^{(2)}(\tau)$ is completely independent of τ , thus we can write $g^{(2)}(\tau) = g^{(2)}(0)$.

Considering the general expression of the photon number variance $(\Delta n)^2 = \bar{n}^2 - \bar{n}$, we may express the second order coherence degree in terms of the photon number variance:

$$g^{(2)}(0) = \frac{(\Delta n)^2 + \bar{n}^2 - \bar{n}}{\bar{n}^2} = 1 + \frac{(\Delta n)^2 - \bar{n}}{\bar{n}^2} \quad (35)$$

We already know that the variance of a pure $|n\rangle$ state, ($n = \bar{n} = 1, 2, \dots$) vanishes, therefore

$$g^{(2)}(0) = 1 - \frac{\bar{n}}{\bar{n}^2} = 1 - \frac{1}{\bar{n}} \quad (36)$$

obtaining $g^{(2)}(0) = 0$ in the case $n = \bar{n} = 1$.

More in general, since $(\Delta n)^2 \geq 0$, it must be $\bar{n}^2 \geq \bar{n}$ and the following inequality holds for photon number states:

$$g^{(2)}(0) \geq 1 - \frac{1}{\bar{n}} \quad (\bar{n} \geq 1) \quad (37)$$

The approach based on the particle aspect of light accounts for the occurrence of the same values of the degrees of second order coherence of the other photon number distributions, already examined in the frame of classical wave theory. By referring to (35) the corresponding results are the following:

- Chaotic light (super-Poissonian statistics): $\Delta n^2 = \bar{n}^2 + \bar{n} \Rightarrow g^{(2)}(0) = 2$; $g^{(2)}(\infty) = 1$ (either collision or Doppler broadened)
- Coherent light (Poissonian statistics): $\Delta n^2 = \bar{n} \Rightarrow g^{(2)}(\tau) = 1$ (whatever the value of τ)
- Nonclassical light (sub Poissonian statistics): $\Delta n^2 \leq \bar{n} \Rightarrow 1 - \frac{1}{\bar{n}} \leq g^{(2)}(0) \leq 1$

These results are summarized in Fig. 7, where the degree of second order coherence, expressed as a function of $\bar{n}$ is reported for chaotic, coherent and photon number nonclassical light. Nonclassical states corresponding to the inequality: $1 - \frac{1}{\bar{n}} \leq g^{(2)}(0) < 1$ are identified by the gray region in Fig. 7 and the pure number states $|n\rangle$ are given by the yellow dots in the same Figure.

In the same figure we also show the behavior of the degree of second order coherence $g^{(2)}(0) = 3 + \frac{1}{\bar{n}}$ of the *squeezed vacuum state* whose variance is $(\Delta n)^2 = 2\bar{n}(\bar{n} + 1)$. Squeezed states of light are another example of light which noise can be below the limits set by quantum mechanics. The photon-number fluctuations in squeezed vacuum state light are thus classified as super Poissonian.

Fig. 7 Degree of second-order coherence expressed as a function of $\bar{n}$ for different kinds of light states.

Fig. 8 Hanbury Brown-Twiss apparatus.

Brown-Twiss correlations – Photon bunching and photon antibunching

The measurements of the second order coherence degree are based on the original experimental apparatus invented by Hanbury Brown and Twiss (HBT) for stellar interferometry purposes. Indeed, the original HBT experiment (Hanbury Brown and Twiss, 1956) was carried out to measure the angular diameter of stars by the observation of spatial coherence effects. The corresponding setup is schematically illustrated in Fig. 8.

Quasi-monochromatic radiation, properly selected in the single spatial mode, is impinging on a symmetric BS, so that half of the original intensity $I_1(t)$, is directed toward detector D_1 , the other half, $I_2(t)$, goes toward detector D_2 . The two output currents, i_1 and i_2 , are directly proportional to the intensities $I_1(t)$ and $I_2(t)$, replicating the fluctuations of the optical signal. The output detector signals are used to determine, by means of a correlator, the average of the product of $I_1(t)$ and $I_2(t + \tau)$, with the variable delay τ setted through an electronic time delay generator. This operation allows to measure the correlation of intensity fluctuations. By assuming a stationary field, $\overline{I_1(t)} = \overline{I_2(t + \tau)}$, and detectors with instantaneous response time, in the hypothesis for both detectors of a null optical delay with respect the BS, we have:

$$g_{12}^{(2)}(\tau) = \frac{\overline{I_1(t)I_2(t + \tau)}}{\overline{I_1(t)}\overline{I_2(t)}} = \frac{\overline{I(t)I(t + \tau)}}{\overline{I(t)}^2} \quad (38)$$

By this scheme, any measurement affected by temporal or spatial coherence of the light can be performed since the correlation measurements between i_1 and i_2 allow to evaluate in general the second order coherence function $g_{12}^{(2)}(r_1, t_1; r_2, t_2)$.

By considering the light beam impinging on the BS as a stream of photons $g_{12}^{(2)}(\tau)$ is expressed in terms of the number of counts registered in D_1 and D_2 , namely m_1 and m_2 :

$$g_{12}^{(2)}(\tau) = \frac{\overline{m_1(t)m_2(t + \tau)}}{\overline{m_1(t)}\overline{m_2(t)}} \quad (39)$$

This expression corresponds to the number of simultaneous counts registered as a function of τ in a certain temporal window, normalized to the product of the average number of counts in the two detectors. Thus, in the photon interpretation of light the average number of the measured coincidences becomes relevant rather than the correlation of the intensities.

An alternative way to measure the second order statistical properties of a light is also used, namely the Mandel Q-parameter:

$$Q = \frac{(\Delta n)^2 - \bar{n}}{\bar{n}} = \frac{\overline{n(n-1)} - \bar{n}^2}{\bar{n}} = \bar{n}[g^{(2)}(0) - 1] \quad (40)$$

It comes out that nonclassical states lie within the region $-1 \leq Q < 0$, coherent light and chaotic light are identified by the values $Q = 0$ and $Q = \bar{n}$, respectively.

We are now able to understand what happens when a stream of photons impinges on the BS. While in the intensity classical picture given in (27) the intensity splits in half on the BS whatever its value, in the particle picture there is a 50% probability that each photon is reflected or transmitted by the BS and goes toward a detector or the other (Grangier et al., 1986). In case it is separated in time from the other photons the probability of simultaneous coincidences at $\tau = 0$ vanishes and grows for $|\tau| \neq 0$. This result, a signature of the quantum nature of light, corresponds to the so-called *photon antibunching*.

Fig. 9 Sequence of photons for: antibunched, random and bunched light.

Let's now consider the case of bunches of photons in the photonic stream. This determines a higher probability of coincidences at short delays with respect to what happens for larger values of τ . This case, corresponding to the so-called *photon bunching*, is just the translation into quantum language of the kind of intensity fluctuations occurring in the classical description of chaotic light.

Coherent light corresponds to the case of a *random* temporal sequence of photons. In the classical picture it has no intensity fluctuations, thus no photon bunches are expected in the quantum picture. The average number of coincidences is constant with τ .

The three cases are shown in Fig. 9.

Photon bunching and photon antibunching represent a further way to classify the different kinds of light. Sub-Poissonian photon statistics and photon antibunching are genuine quantum feature with no classical analog. They appear frequently together in nonclassical light and could be interpreted as different manifestations of the same quantum phenomenon. This is not the case; in fact, it has been demonstrated that sub Poissonian statistics doesn't necessarily imply photon antibunching but can be accompanied in some case by photon bunching (Zou and Mandel, 1990). In general, they must be considered as distinct phenomena.

Basic photon statistics at beam splitters

The optical beam splitter is an essential tool present in many experiments in which the ambivalent nature of light, wave, or stream of particles, is manifested.

In this section a few examples are discussed, regarding situations in which one or more photons are incident in the input ports of a BS or a combination of more BSs. Depending on the initial conditions the output solutions are classical or genuinely quantum.

In the classical wave description of first order interference, the meaning of BS is very simple, while things are expected to be more complex when the quantum statistical behavior of photons is considered. In the language of quantum optics, the lossless BS is treated as a *unitary operator* in which the phases of the transmission and reflection coefficients are $\theta = 0$ and $\varphi = \frac{\pi}{2}$. A few situations are below examined (Weihs and Zeilinger, 2001).

a) Stream of equally spaced single photons incident on a beam splitter from the same input port

Let's consider a sequence of equally spaced identical photons shining on the input mode a of a symmetric and lossless BS, while no photon is impinging on the other input arm b (see Fig. 10). In the quantum language, we may write:

$$\hat{a}^\dagger |0\rangle_a = |1\rangle_a \rightarrow \frac{1}{\sqrt{2}} [|1\rangle_c |0\rangle_d + i |0\rangle_c |1\rangle_d] \quad (41)$$

where the factor i accounts for the phase shift $\frac{\pi}{2}$ gained by the field from the reflection on the BS. The expression given in (41) is equivalent to say that the output state is a *superposition state* of the single photon in modes c and d , similarly the vacuum state $|0\rangle$ in the input mode b is divided with equal probability in modes c and d . Since for each photon the probability of being transmitted or reflected is 50% two random sequences of photons can be registered in the two BS output modes. The noise introduced by the beam splitter in the output modes c and d is called *partition noise*. As an equivalent point of view the added noise is coming from the vacuum state $|0\rangle$ incoming in the input mode b of the BS.

b) Stream of single photons incident on an input port of a Mach-Zehnder interferometer

Fig. 10 Single photon partition due to the BS introduces random noise in the output photon streams.

Fig. 11 Single photons incident on a Mach Zehnder interferometer.

Fig. 12 Two photons shining a BS from the same input port.

Regarding this case (see Fig. 11), we have:

$$\begin{aligned} \hat{a}^\dagger |0>_a &= |1>_a \rightarrow \frac{1}{\sqrt{2}} [|1>_c |0>_d + i e^{i\phi} |0>_c |1>_d] \rightarrow \frac{1}{2} [0>_e |1>_f + i |1>_e |0>_f + i e^{i\phi} |1>_e |0>_f - e^{i\phi} |0>_e |1>_f] \\ &= \frac{1}{2} [|0>_e |1>_f (1 - e^{i\phi}) + i |1>_e |0>_f (1 + e^{i\phi})] \end{aligned} \quad (42)$$

It's easy to obtain that the probabilities to find the photon in the output modes e or f are:

$$p_e = \cos^2 \frac{\phi}{2} \quad p_f = \sin^2 \frac{\phi}{2} \quad (43)$$

This result demonstrates once more the presence of interference fringes in the output modes e and f even at the single photon level, as with a classical light beam.

The number of photons is maximized in either one of the two output modes for $\phi = n\pi$ ($n = 0, 1, 2, \dots$), depending on the parity of n . In these cases, the noise introduced by the MZI vanishes while it is maximized in both the output modes e and f for $\phi = (2n + 1)\frac{\pi}{2}$, ($n = 0, 1, 2, \dots$).

c) Two independent photons incident on a beam splitter from the same input port

The case of two independent particles, shining the same input port of a BS (see Fig. 12), is quite simple to study. Considering the input state and its evolution through the BS we find:

$$|1>_a |1>_b \rightarrow \frac{1}{2} (|1>_c |0>_d + i |0>_c |1>_d) (|1>_c |0>_d + i |0>_c |1>_d) \quad (44)$$

It's easy to find from (44) that the partition probabilities of the two particles at the output of the BS follow the rules of the classical binomial distribution:

both photons on mode 3: $p = 0.25$.

both photons on mode 4: $p = 0.25$

one photon each in modes 3 and 4: $p = 0.50$

Even in this case the BS adds new random noise to the system.

d) Two independent photons incident on a beam splitter in a superposition of input ports

In this case (depicted in Fig. 13) the input state is expressed as a coherent superposition of two possible events:

$$\frac{1}{\sqrt{2}} (|1>_a |1>_a + e^{i2\phi} |1>_b |1>_b) \quad (45)$$

Fig. 13 Two photons enter together in either one of the input ports of BS.

Fig. 14 two indistinguishable photons, one in each input port of the BS.

Considering the evolution for each photon entering through mode a or b toward the output modes c and d , it is easy to find that the output state is a function of the global phase, thus the following possibilities are expected:

- two photons in the same output mode c , or d . In this case the noise is the same that they have in the input mode, a or b .
- one photon in mode c and the other in mode d , or viceversa, with suppression of noise in both cases.

e) Two indistinguishable photons incident on the BS, one from port a and one from port b

In the case of Fig. 14 two *indistinguishable* particles are incident on a symmetric BS ($r = t$) from the ports a and b .

The concept of indistinguishability means that, *in principle*, it is *impossible* to know where each particle is coming from when they arrive on the BS. This condition is guaranteed if the two photons are *identical* in terms of frequency, bandwidth, $\mathbf{k}$ vector, polarization, and arrival time. The transformation of the input field in the BS is expressed as:

$$\hat{a}^\dagger \hat{b}^\dagger |0\rangle = |1_a, 1_b\rangle \rightarrow \frac{1}{2} (c^\dagger + id^\dagger)(ic^\dagger + d^\dagger) |0\rangle = \frac{i}{2} [(c^\dagger)^2 + (d^\dagger)^2] |0\rangle = \frac{1}{2} [|2_c\rangle |0_d\rangle + |0_c\rangle |2_d\rangle] \quad (46)$$

The output state given in (46) is the result of a cancelation of the $c^\dagger d^\dagger$ and the $-d^\dagger c^\dagger$ terms and can be considered as an entangled state, corresponding to a coherent superposition of having 2 photons in the output port c and 0 photon in the output port d , or 0 photons in c and 2 photons in d . The state given in (46) has great relevance for *quantum metrology*.

The complete absence of photon coincidences between c and d is the signature of a radical change of the BS partition, from the classical binomial to the quantum Bose-Einstein statistics. This is the essence of the fundamental Hong-Ou-Mandel experiment (Hong et al., 1987), an effect without any classical analog.

Since the photons are not perfectly monochromatic, the temporal region in which a coincidence dip is registered corresponds to the photon wave-packet, as shown in Fig. 15. In ideal conditions, coincidences vanish, with a consequent visibility of 100% for a temporal delay $\Delta t = 0$, i.e. when the two photon wave-packets are coincident. Note that, due to the Poissonian distribution, the theoretical limit for the Hong-Ou-Mandel visibility is 50% for indistinguishable weak coherent photon states (Kim et al., 2020).

More in general, considering the BS as a device able to perform a symmetric partition of two indistinguishable input particles, the input state can be expressed in terms of a superposition of the equally possible events $|1_a, 1_b\rangle$ and $|1_b, 1_a\rangle$. It has the form of a symmetric state in the case of two incident bosons:

$$\frac{1}{\sqrt{2}} [|1_a, 1_b\rangle + |1_b, 1_a\rangle] \quad (47)$$

or of an antisymmetric state in the case of two incident fermions

$$\frac{1}{\sqrt{2}} [|1_a, 1_b\rangle - |1_b, 1_a\rangle] \quad (48)$$

Fig. 15 Coincidence dip registered in a Hong-Ou-Mandel experiment.

Here we use the (+) or the (−) sign depending on the symmetric or antisymmetric nature of the state upon interchange of the particles.

The states corresponding to the output ports of the BS are:

$$\frac{1}{\sqrt{2}} [|1_c, 1_c\rangle + |1_d, 1_d\rangle] \quad (49)$$

for two incident bosons, and:

$$\frac{1}{\sqrt{2}} [|1_c, 1_d\rangle - |1_d, 1_c\rangle] \quad (50)$$

which is equivalent to the case of two incident fermions.

The result shown in (49) is equivalent to the one given in (46). Photons are bosons, therefore in the Hong-Ou-Mandel experiment the two input photons occupy the same output port, c or d (*bosonic coalescence*). The opposite would happen in the case of two fermions, that, following the Fermi-Dirac statistics, occupy separately the output ports c and d in agreement with the Pauli exclusion principle. In this case, as shown in (50), we expect a peak of coincidences instead of a dip. This effect can be simulated by a polarization entangled state of two photons, expressed as:

Fig. 16 Dip-peak (triplet-singlet) transition occurring in a 2-photon polarization entangled state.

$$\psi = \frac{1}{\sqrt{2}} [(|H_a, V_b\rangle + e^{i\theta}|H_b, V_a\rangle)] \quad (51)$$

This state allows to simulate the behavior of two bosons for $\theta = 0$ (symmetric triplet state) or two fermions for $\theta = \pi$ (antisymmetric singlet state). An experimental example of this simulation is shown in Fig. 16 where the dip-peak transition ($\theta = 0 \rightarrow \theta = \pi$) for the entangled state (51) is reported (Barbieri et al., 2005).

In this section we have presented some of the possible examples that can occur when one or more particles are incident on a beam splitter. Some of these results open the way to the understanding of some of the modern quantum information protocols.

Conclusion

Aim of this chapter was to investigate optical fluctuations to understand the intimal properties of light in its various manifestations, both classical and quantum. We have carried out this study by analyzing first the different statistical distributions governing the behavior of light and discussing how a non-perfect detection of photons may affect the statistics of the photonic beam.

To quantify the statistical properties of the different kinds of light we have introduced the basic elements of the coherence theory, at the first and second order, examined both in the classical and quantum contexts.

The behavior of light has been also classified in terms of the concept of bunching and antibunching. The properties of the beam splitter and its fundamental role in the statistics of photonic beams have been finally discussed.

References	189

Abstract

A “point defect” is an atomic-scale imperfection in an otherwise perfect crystal. It thus may be contrasted with an “extended defect” which involves a large portion of the crystal and which is important in determining its mechanical properties. Much of solid-state technology is associated with point defects, and indeed this topic is central to many of the articles in this compilation. Hence, this article will address general properties of point defects in condensed matter, while other articles delve into more specific properties and applications. Kaxiras (2003) and Kittel (2004) are two general texts on condensed-matter physics that include basic elements of this article, while Tilley (2018) treats a wide array of topics related to point defects, including applications.

Glossary

Antisite defect An atom on the “wrong” site in a crystal that contains more than one type of chemical constituent.

Atomic diffusion The motion of an atom over a macroscopic distance as the result of a series of individual microscopic motions which are statistical in nature.

Chemical impurity An atom, ion, or (small) molecule that is chemically different from the perfect-crystal constituents.

Color centers Point defects in insulators that generate optical activity in the visible.

Configuration coordinate diagram Plot of energy vs. atomic position for a molecule or defect.

Deep defects Defects in semiconductors or insulators in which the electron or hole is strongly bound and is not likely to be unbound at room temperature.

Doping The introduction of chemical impurities into a crystal.

Extended defect An imperfection that extends through a large portion of a crystal.

F center An electron trapped at a halogen-ion vacancy in an alkali halide crystal.

Fermi energy The chemical potential of a solid.

Frenkel defect A vacancy-interstitial pair.

Hydrogen passivation The change of the nature of the electrical properties of defects by the incorporation of hydrogen into the defect.

Interstitial An atom or ion at a position other than a perfect-crystal site.

n-type A semiconductor with an excess of donors.

Negative-U A situation in which the “effective” Coulomb interaction between electrons or holes is negative

p-type A semiconductor with an excess of acceptors.

Perfect crystal A periodically repeated array of identical building blocks such as atoms or arrays of atoms.

Perovskite oxides Compounds of the type ABO_3 , where “A” and “B” represent different cations.

Point defect An imperfection in a perfect crystal that is of the order of atomic size.

Schottky defect An isolated vacancy in an otherwise perfect non-ionic crystal.

Shallow donors and acceptors Defects in semiconductors in which the electron (donor) or hole (acceptor) is weakly bound and is likely to be unbound at room temperature.

Stokes shift The energy difference between absorption and emission bands.

Substitutional defect A defect that occurs on a perfect-crystal -atom site.

Vacancy The absence of an atom or ion from its perfect-crystal site.

Zero-phonon transition An optical transition from the zero-point vibrational level of one electronic state to the zero-point level of another state.

Key points

- Atomic-scale defects, such as impurities and missing or displaced atoms, are called “point defects” and are commonplace in otherwise regular, perfect crystals and glassy materials.
- Such defects are responsible for most of the properties that have made materials useful in both ancient and modern technologies.
- These defects may introduce both desirable and undesirable properties, depending on the applications.
- Understanding the nature, the effects, and the control of these defects is therefore of great importance.

Introduction: Types of point defects

In a solid that contains no chemical impurities, the fundamental intrinsic point defects are vacancies, interstitials, and antisites. A “vacancy” (also called a “Schottky defect”) is a missing atom from a normally occupied site, while an “interstitial” is an extra atom in a normally unoccupied site. A “Frenkel defect” results when an atom is moved from a normal site to an interstitial site. In compound solids (e.g., GaAs), an “antisite” defect exists when an atom of one of the constituent elements is located at a site normally occupied by that of a different element.

A compound solid has another degree of freedom that can lead to vacancies and interstitials, namely chemical stoichiometry. A slight abundance of one of the components can lead to interstitials of that component, vacancies of another component, or antisites. This issue is particularly relevant in complex oxides such as perovskites, in which standard preparations or heat treatments often yield non-stoichiometric crystals.

Chemical impurities may be present substitutionally (placed on a normal atomic position in the crystal) or interstitially. Furthermore, the presence of certain chemical impurities may induce the existence of vacancies or interstitials. For example, if a second-column impurity ion such as Ca^{2+} substitutes for Na^+ (a first-column ion) in an insulating ionic solid such as NaCl, it is likely that there will be a Na^+ vacancy nearby, in order for overall charge neutrality to be satisfied.

Particularly in semiconductors, but also in insulators, specific point defects may exist in different charge states. The charge states will clearly influence the electrical and optical properties of the solid. Charge states may be changed by varying the chemical potential (Fermi energy) of the solid, by various photoionization processes, or by charge injection.

While the simplest notion of atoms in solids is that of spheres of different sizes, an understanding of point defects (especially in nonmetals), in fact, relies heavily on chemical bonding ideas. For example, interstitials in semiconductors almost never simply sit at empty sites, interacting weakly with their neighbors. Rather, the interstitial atom and its neighbors reorganize their bonding and their positions, often forming the so-called split interstitial whose structure is governed by chemical bonding concepts. Similarly, a cation atom next to a cation vacancy in certain oxides (e.g., Ga_2O_3) may shift position to yield a cation interstitial between two cation half-vacancies (Varley et al., 2011; Kyrtos et al., 2017).

Control of point defects

The control of point defects in solids is a central role of materials physics, and it is often the ultimate source of success or failure in a particular application.

The first step in point defect control is in the crystal growth process. It is at this point that desired impurities may be introduced and undesired impurities may be avoided. The outcome depends on the purity of the starting material, the detailed growth process, and the growth environment. In general, the growth environment, including chemicals used in the process, will lead to some incorporation of impurities, whose concentration in most cases can be made small enough to not interfere with the applications of the material.

Even an elemental solid such as silicon, prepared with care, will contain intrinsic defects as a consequence of thermal equilibrium. Although a perfect crystal structure represents the most stable arrangement energetically, in thermal equilibrium a number of defects will exist as determined by Boltzmann statistics:

$$N_D = BN \exp(-AE/kT). \quad (1)$$

Here N_D is the number of defects, N the number of atomic sites, and A and B are dimensionless factors of order 1. E is the energy required to create the defect, k is Boltzmann’s constant, and T is the Kelvin temperature. If, for example, the creation energy is 0.35 eV, the room-temperature equilibrium fraction of defects can be $\sim 10^{-6}$, large enough to have noticeable effects. Commonly, the creation energy is larger, but even then, exposure of the solid to high temperatures during growth or processing can lead to a

significant fraction of intrinsic defects, which can be “frozen in” at concentrations appropriate to the higher temperature if cooling occurs faster than thermal equilibrium can be established.

In some cases, additional thermal processes may reduce the defect concentration through annealing. On the other hand, thermal treatments that are necessary for the construction of complex semiconductor devices may yield unwanted outcomes relative to the point defects in portions of the device, such as thermally stimulated diffusion of impurity atoms from one region of the device to another.

In thin films, such as those that occur in semiconductor devices, applied electric fields may also lead to changes in the location or configuration of point defects. Electric-field-induced diffusion of atoms or ions may occur. Or, trapping of mobile charges may lead to changes in defect configurations.

Point defects may be created or modified by external ionizing irradiation, either by photons or by high-energy particles. A number of different processes may take place, depending on the material and the properties of the radiation. Heavy particles (such as neutrons or α -particles) of sufficient energy can displace atoms in the crystal by momentum-and-energy-conserving “billiard-ball” collisions. For lighter particles such as electrons or γ -rays, the requirements of both energy and momentum conservation in this process require very high energies for the incoming particle.

In some non-metallic crystals, irradiation can introduce point defects by simply ionizing atoms or ions, in which case the energy required is much more modest, namely the band gap, of order several electron volts. In such cases, the defect creation occurs via a chemical reaction between the ionized atom, or the atom in an excited state, and one or more other atoms in its vicinity.

Point defect diffusion

Point defect diffusion is a process in which a defect moves a macroscopic distance as the result of a series of short-range, statistical motions. Many specific mechanisms of defect diffusion may exist, depending on the defect or defects, the host, and other conditions such as temperature and external fields. The interaction of point and extended defects may lead to large enhancements of point defect diffusion. Detailed treatments of diffusion may be found in [Borg and Dienes \(1988\)](#), [Flynn \(1972\)](#), and [Murch and Nowick \(1984\)](#).

An impurity at an interstitial site is considered, for example. Thermally activated motion over a potential barrier will be required for the impurity to move to an equivalent nearest-neighbor site. If there is just one impurity and there are no additional fields, its net motion will be a “random walk”; its long-range displacement will be hampered by its tendency to jump back toward, in addition to away from, the initial site, and neither direction will be favored. Calculations using statistical methods show that the net distance traveled by the impurity will vary as the square root of time.

If, however, an external field yields a net force in one direction, then the probability of jumps in that direction will be greater than the probability of jumps in the reverse direction, so there will be a net motion of the impurity in the direction of the net force.

Furthermore, diffusion can take place in the absence of external fields if there is a concentration gradient of impurity atoms. An impurity will tend to jump from a region of higher concentration to a region of lower concentration, since in a direction of higher concentration the neighboring interstitial sites are more likely to be already occupied. This effect is described by Fick’s first law:

$$J(x) = -D \frac{\partial C(x)}{\partial x} \quad (2)$$

Here $J(x)$ is the impurity flux in the x -direction, $C(x)$ is the impurity concentration, and D is the diffusion coefficient. The diffusion coefficient D contains all the material properties, and it is also a function of temperature. Since the diffusion process involves thermal motion over a barrier, the diffusion coefficient D often varies with temperature, T , in a way similar to Eq. (1):

$$D = D_0 \exp(-\Delta E/kT) \quad (3)$$

Here, ΔE is the height of the potential barrier and k is Boltzmann’s constant.

In crystals of low symmetry, such as rutile or monoclinic oxides, the diffusion coefficient for certain point defects will generally show a strong dependence on crystal direction ([Johnson et al., 1975](#)).

Point defects in normal metals and superconductors

Because metals contain nearly-free electrons, charge neutrality in the region of a point defect will automatically be satisfied. Hence issues such as charge-compensating defects or charge-state effects, which are of major importance in nonmetals, are not relevant in metals. Nevertheless, point defects are still of importance in affecting the properties of metals. Two examples are mentioned here: electrical properties and magnetic properties ([Kaxiras, 2003](#); [Kittel, 2004](#); [Tilley, 2018](#)).

Even though charge neutrality in the region of point defects in metals exists, point defects still scatter conduction electrons. This is particularly important at low temperatures, where phonon scattering in the perfect crystal is reduced while impurity scattering remains.

Magnetic impurities can be important in both magnetic and nonmagnetic metals. In the latter case the magnetic moment of the impurity is partially, but not completely, screened by the conduction electrons. In the former case, interactions between the magnetic atoms are important and will help determine the magnetic properties of the defective material.

In most cases, point defects have negative effects on superconductivity, since superconductivity involves coherent effects between charged particles. In high- T_c superconductors, however, impurities can increase the number of mobile charges. Furthermore, impurities have been of some use in studying the mechanisms for superconductivity.

Point defects in semiconductors

Semiconductors are useful in electronics because it is possible to add impurities in a way that leads to specified concentrations of mobile charges that, in turn, can carry current. Useful background material on semiconductors may be found in [Jackson and Schröter \(2008\)](#), [McCluskey and Haller \(2012\)](#), and [Yu and Cardona \(2010\)](#).

The deliberate addition of impurities is called “doping.” In the simplest elemental semiconductors, such as silicon (a group IVb element), each atom has four valence electrons and forms bonds to four neighbors. If a phosphorous (a group Vb element) atom replaces a silicon atom, four of the phosphorous valence electrons form bonds, and the fifth is only weakly bound to the phosphorous atom. This weakly bound electron can be thermally ionized at normal temperatures, yielding a conduction electron. The result is called n-type conduction.

If, on the other hand, a boron (a group IIIb element) atom replaces a silicon atom, a valence electron is needed to form bonds with the four neighbors, leaving a missing electron—a “hole”—in the valence band, weakly bound to the boron. This hole can be thermally ionized at normal temperatures, yielding a positively charged conducting “particle.” The result is called p-type conduction.

This simple picture does not always hold. For example, nitrogen is also a group Vb element, but a nitrogen atom substituting for a silicon atom does not yield a weakly bound electron. Rather, the nitrogen relaxes from the center of the substitutional site and forms bonds with the neighboring silicons in which all the electrons are involved and none are left to be weakly bound. This example shows that in general, localized (“deep”) and delocalized (“shallow”) defect states may coexist, and which configuration is more stable depends on details.

In some cases, doping in compound semiconductors (such as GaAs) follows similar logic. For example, silicon in GaAs is amphoteric; if Si replaces Ga the system is n-type, whereas if it replaces As the system is p-type.

It has been found difficult to achieve p-type doping in a number of compound semiconductors. For example, most divalent impurities substituting for the cation in the nitrides lead to hole states that are too deep in energy to be ionized at room temperature. In some cases p-type doping may be overcompensated by unintentional n-type defects.

Along with deliberately introduced dopants, many other kinds of defects may occur in semiconductors. Some are relatively benign; for example, substitutional C in Si does not trap electrons or holes; so it may occur in a relatively large concentration and have little effect on the electronic properties of Si. Others may themselves trap electrons or holes, or they may combine with dopants in a way that “passivates” the electrical activity of the defect. For example, substitutional B in Si may combine with a H atom, resulting in a B-H pair in which the H is bond-centered (i.e., located within a B-Si bond) in the positive or the neutral charge state. In this configuration, the H atom supplies the fourth bonding electron, so there is a no weakly-bound hole and p-type conduction is suppressed.

Hydrogen is a common and significant impurity in semiconductors ([Stavola and Fowler, 2018](#); [Van de Walle, 2007](#)). There is considerable evidence that in a number of oxide semiconductors (such as SnO_2), interstitial H or H at an anion vacancy may lead to n-type conduction. Semiconductor processing involves compounds that contain hydrogen, so it is commonly present. Hydrogen is also amphoteric; it may passivate both donors and acceptors. In fact, hydrogen is, in many cases, a “negative-U” defect. This means that it will never occur as a neutral atom in thermal equilibrium; for any pair of hydrogen atoms (in general, well-separated), the sum of the energies of H^+ and H^- is lower than the energy of two neutral H’s, and the charge state (plus or minus) will depend on the location of the Fermi level. If in fact the H’s are mobile, it is possible that interstitial H_2 molecules will form, whose energy is still lower and thus represents the most stable state.

Defect motion is of great importance in semiconductor technology, and it has been widely studied. As noted earlier, atomic diffusion may occur during high-temperature processing, and in semiconductors this may yield deleterious effects on resulting devices. Processes that involve impurities coupled with intrinsic defects are common. For example, a substitutional Au atom in Si can switch places with an interstitial Si, forming an interstitial Au, which in turn has a very high diffusivity.

An important phenomenon in optical and some electrical applications is recombination-enhanced diffusion. In some situations, the energy gained from the recombination of an electron and a hole is sufficient to allow atomic motion over potential barriers. For example, optical excitation in ZnSe can induce a diffusion jump of an interstitial Zn atom.

Diffusion of impurity atoms in semiconductors may be enhanced by electric fields. For example, N and B may be induced to diffuse in SiC under high temperature conditions in the presence of a field associated with a built-in p-n junction in the material.

Another important issue is the effect of charge states on diffusion. Because the structure and energetics of defects may be strongly dependent on charge states, so may the diffusion coefficient. Hence, atomic diffusion phenomena observed in n-type and in p-type semiconductors may be quite different.

Point defects in insulators

Insulating solids share with semiconductors the existence of a bandgap, a region of forbidden energy between filled and empty electronic states. They also share some physics, such as the possible existence of defect states of different charge. Topics related to this section are treated by [Fowler \(1968\)](#), [Hayes and Stoneham \(1985\)](#), [Pajot \(2010\)](#), and [Pajot and Clerjaud \(2013\)](#).

A fundamental distinction between insulators and semiconductors is that defect states in insulators are almost never sufficiently shallow in energy to provide charge carriers at normal temperatures. Hence, defects in insulators are almost always “deep.”

There are many distinctions between insulators and semiconductors concerning important properties and applications. For example, the bandgaps of insulators span the energy range of visible photons, so defects in insulators may have important optical properties (Fowler, 1968). Indeed, in the early German literature on defects in alkali halides (e.g., NaCl), such defects were called “farbzentren” (or “color centers”). Many precious gems have significant colors because of naturally occurring point defects in an insulating host. One result of these properties was the invention of the ruby laser, and insulator hosts have proven useful in connection with other optical devices and lasers as well.

Point defects in nonmetallic crystals will, if they have energy levels within the gap between the valence and conduction bands, lead to characteristic optical absorptions that involve the excitation of electrons or holes from a ground state to an excited state. In many cases, there is also luminescence as the excited defect returns to the ground state.

The general theory of optical absorption, as well as some aspects of luminescence, is similar for deep semiconductor and insulator defects. In both cases, the electron-phonon interaction is involved. The defect in its ground electronic state has neighboring atoms that vibrate about sites whose equilibrium positions are determined, in part, by the defect wave function. When the defect is electronically excited, the neighboring atoms, responding to a new defect wave function, relax to new equilibrium positions. This process may be represented by a configuration coordinate diagram (Fig. 1) of energy, E , vs. an average position of the neighboring atoms, R . This idealized case consists of two displaced parabolas representing the harmonic energy of the vibrating atoms in ground (m) and excited (k) states. η and γ denote the quantized vibrational levels associated with the parabolas. An optical transition, in general, involves a change of both electronic and vibrational quantum numbers.

In the weak-coupling limit, where the excited-state parabola is nearly above that of the ground state, the strongest transitions involve no change in vibrational quantum number. In this case, at low temperature, if only the zero-point vibrational level of the ground state is occupied, the strongest transition will be a sharp “zero-phonon” transition from A to C to the zero-point level of the excited state.

In the strong-coupling limit shown in Fig. 1, with both horizontal and vertical displacements of the parabolas, the zero- and few-phonon transitions are weak because the vibrational wave functions of the low-lying displaced oscillators do not overlap strongly, and the optical absorption is characterized by a broad multi-phonon transition A to B which is approximately vertical in the configuration coordinate R .

In the absence of nonradiative processes, the excited defect will luminesce, emitting a photon as it returns to the ground state. In general, the radiative lifetime is at least several orders of magnitude longer than the vibrational relaxation rates, so the excited defect will relax to its lowest vibrational state; for example, at low temperature it will relax to the zero-point state C before the defect radiates. In the weak-coupling limit the zero-phonon line C to A will be identical to that for absorption, while few-phonon lines will lie at lower photon energy (in contrast to absorption, where they lie at higher energies). In the strong-coupling limit the broad multi-phonon emission C to D will be “Stokes-shifted” to lower photon energy from that for absorption, as shown in Fig. 1.

In the strong-coupling limit, then, the electron-phonon coupling has substantial effects. For example, for an electron trapped at a Cl^- vacancy in KCl (an F center), the optical absorption peak at low temperature is at 2.3 eV with a width at half-maximum of 0.16 eV, while the luminescence peak is at 1.2 eV with a width of 0.26 eV.

Semiconducting oxides

Semiconducting oxides represent an important class of materials that combine properties of insulators and semiconductors. While the energy difference between valence and conduction bands is large, typical for an insulator, n-type doping is nevertheless possible by defects that do not lead to optical absorption in the visible range. These transparent conducting oxides have many applications, such as touch screens on cell phones. Materials having these properties include ZnO, In_2O_3 , SnO_2 , and Ga_2O_3 (He, 2020; Yu and Cardona, 2010).

Fig. 1 Configuration coordinate diagram for a model system.

Point defects for quantum computing

Point defects, one in particular, are in serious consideration as vehicles for quantum computing. The leading candidate which has been widely studied is a complex in diamond that consists of a carbon vacancy adjacent to a nitrogen impurity, the so-called diamond NV center. This defect combines optical and spin properties in a particular way to make it a very attractive prospect. Details of these processes and prospects may be found, for example, in Childress and Hanson (2013).

Conclusion

Point defects in solids are of great importance and can have a wide variety of properties and applications. Other articles in this compilation delve more deeply into these topics. Internet searches under “crystal point defect” will provide up-to-date connections, as well.

Abstract

Many modern technological systems would not exist without synthetic single crystals. Therefore, the technology to prepare and to produce bulk single crystals—which is called “crystal growth”—is one of the current key technologies. This article gives an overview about the techniques which are used to grow bulk single crystals of inorganic materials. This includes melt, solution and vapor growth techniques.

Key points

- Overview of melt growth techniques including principles and typical crystal materials
- Overview of solution growth techniques including principles and typical crystal materials
- Overview of vapor growth techniques including principles and typical crystal materials

Introduction

Synthetic single crystals are enabler for many modern technological systems. The production of bulk single crystals is called “crystal growth.”

This article gives a brief overview about the techniques which are used to grow bulk single crystals of inorganic materials. More detailed information on the different technologies and materials can be found in Rudolph (2015). The fundamental physical and physicochemical mechanisms which govern the crystal growth processes are treated by Nishinaga (2015). The basics and the methods for growing epitaxial films are described by Kuech (2015). The status of the growth of organic materials can be found, e.g., in Nishinaga (2015).

The structure of the article is sketched in Fig. 1.

[☆]*Change History*: October 2022. J Friedrich updated the chapter. Figs. 24 and 26 are new and Figs. 1, 23, and 25 are replaced by new one.

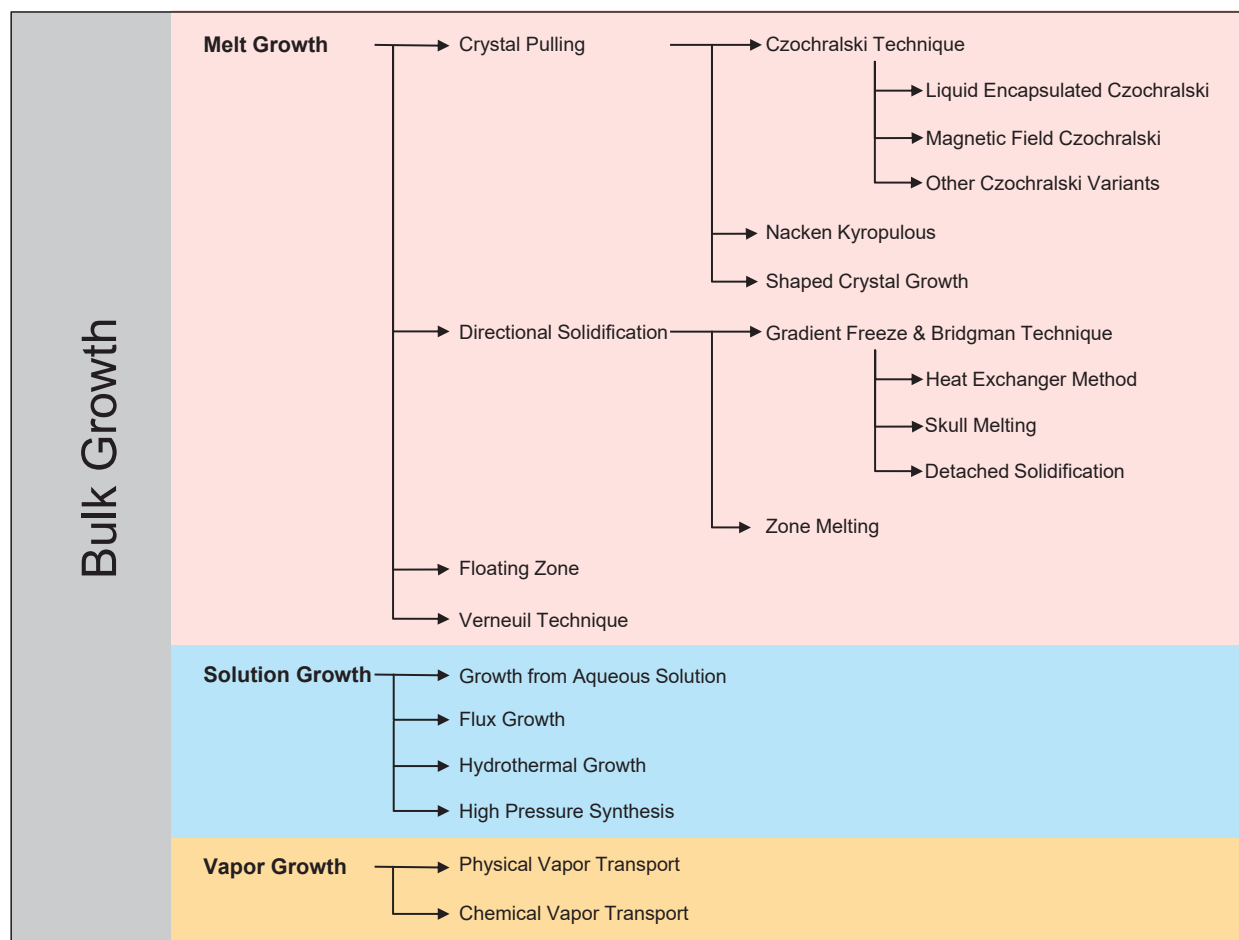

Fig. 1 Overview of methods for bulk crystal growth.

Melt growth

The most frequently used and most important method of producing bulk single crystals is by solidifying the material from its melt (melt growth). In a few cases melt growth is not feasible for certain reasons, e.g., if the crystal to be grown has no congruent melting point or if the melting point or vapor pressure are too high. In these cases the crystals have to be grown either from solutions or from the vapor phase.

Crystal pulling

Czochralski technique

The Czochralski method (Cz) is the most important method for the production of bulk single crystals of a wide range of electronic and optical materials (Fig. 2). At the beginning of the process, the feed material is put into a cylindrically shaped crucible and melted by resistance or radio-frequency heaters. After the feed material is completely molten a seed crystal with a diameter of typically a few mm is dipped from top into the free melt surface and a small portion of the dipped seed is melted. A melt meniscus is formed at the contact interface between seed and melt. Then, the seed is slowly withdrawn from the melt (often under rotation) and the melt crystallizes at the interface by forming a new crystal portion. During the further growth process, the shape of the crystal, especially the diameter, is controlled by carefully adjusting the heating power, the pulling rate and the rotation rate of the crystal. Usually an automatic diameter control is applied. This diameter control is based, either on the control of the meniscus shape (e.g., for silicon) or on the weighing of the crystal (e.g., for GaAs, InP) or of the melt (e.g., for oxides).

In order to control the convective heat and species transport in the melt including the shape of the solid-liquid interface, which is playing one of the most dominant roles in terms of the crystal quality, a proper combination of crystal and crucible rotation is used during the whole process.

The most important technical application of the Cz method is the growth of dislocation-free silicon crystals with diameters up to 300 mm and a weight up to 400 kg in industrial production (see Fig. 3). Silicon crystals with diameters of 450 mm and a weight exceeding 400 kg were already demonstrated (von Ammon et al., 2015). The silicon crystals are used in microelectronics as well as in

Fig. 2 Schematic of the principle of the Czochralski method (left) and illustration of the different steps (a–j) of the Cz process for growing a Si crystal. (a) The polycrystalline feedstock is melted (b) in a crucible. (c, d) Seeding procedure: The seed crystal is dipped into the melt, followed by Dash necking (e), shouldering (f), cylindrical growth (g), growth of end cone (h), lift off (i), cooling down and removing of the crystal (j). After von Ammon W, Friedrich J, and Müller G (2015) Czochralski growth of silicon crystals. In: Nishinaga T, Rudolph P, and Kuech TF (eds.) *Handbook of Crystal Growth*, 2nd ed., pp. 45–104. Amsterdam: Elsevier/North-Holland.

Fig. 4 Examples of typical configurations for magnetic field in the MCz method. (a) transversal; (b) axial; (c) cusp. Gray areas are sections of magnetic coils, the curved lines denote the magnetic field lines.

photovoltaics. The Cz method is also applied to grow on an industrial scale germanium crystal with diameters of typically 150 mm to be used as substrates for III–V multi junction solar cells (Rudolph, 2015), IR optics and gamma ray detectors. Furthermore, several technically important oxide and fluoride crystals like garnets, niobates, tantalates, silicates, vanadates, aluminates, germanates are grown by the Cz method.

The heat and species transport in the melt has a very strong influence on the crystal properties as they are responsible for the uniformity of dopants on the micro- and macro-scale as well as for the shape of the solid-liquid interface and, therefore, for the thermal stress generated in the crystal. During crystal growth the use of stationary or time dependent electromagnetic fields enables the control of the flow in electrically conducting melts (e.g., semiconductors). A Lorentz force is generated in the melt which depends on the magnetic field configuration and leads either to a damping of the flow or to a stimulation of a certain flow pattern. Today, magnetic fields (Fig. 4) are quite common in the industrial production of silicon crystals with 300 mm diameter. More details on the usage of magnetic fields in crystal growth can be found, e.g., in Friedrich (2007).

In order to improve the axial uniformity of the dopant distribution in the grown crystal, the crystal can be grown in such way that the melt volume is kept constant by supplying the solidified portion from a source. Such a source can be realized either by continuously supplying the melt with a feed (Continuous Czochralski method (CCz)) or by placing an inner crucible with holes in a larger outer crucible (Double Crucible Czochralski technique). Although the feasibility of these methods was demonstrated, its use for production of electronic silicon is limited owing to technical and material problems preventing a high yield. Another Cz variant is the so-called “multiple pulling” technique (see Fig. 5). In the multiple pulling Cz method the crucible is kept at melting

Fig. 5 Sketch of a Cz process with repeated use of the crucible by recharging and without cooling down the crucible between growth runs. From Müller G and Friedrich J (2010) Optimization and modeling of photovoltaic silicon crystallization processes, 14th international summer school on crystal growth. *AIP Conference Proceedings* 1270: 255–281.

temperature after the growth process and filled again with silicon after removal of the grown crystal (Müller and Friedrich, 2010). The advantage of this method is cost saving by multiple using of the crucible and saving the time period for cooling down and heating up periods. Today the multiple pulling Cz technique is used in industrial production for solar as well as electronic silicon crystals. More details about Cz growth of silicon crystals can be found in von Ammon et al. (2015).

If the material to be grown has a high partial pressure of one or more components at the melting point, a modified Cz-set-up can be used which is called the Liquid Encapsulated Czochralski method (LEC). In this LEC-set-up a liquid, usually boric oxide, is applied to encapsulate the melt and the crystal in order to prevent the evaporation of a volatile component from the melt and crystal. In this case the pressure of the inertial gas in the growth chamber must exceed the partial pressures of the volatile components. The LEC-technique was historically the industrial production technique for the growth of the compound semiconductors GaAs, GaP, InP, PbSe and PbTe.

However, the low thermal conductivity of the liquid encapsulant causes large temperature gradients and large temperature non-linearities in the growing crystal. This is unfavorable with respect to the crystal quality as a relatively large number of structural defects (dislocations) are generated in the crystal. LEC has therefore often been replaced by the Vertical Gradient Freeze (VGF) technique (see below).

Nacken Kyropoulos method

The Kyropoulos (or Nacken-Kyropoulos) method is rather similar to the Cz method. The main difference is that the crystal is not growing at the top of the melt as in the Cz method but is partly immersed in the melt. In order to extract efficiently the heat from the growing crystal usually a seed with a large diameter is used. Growth is achieved by either lowering continuously the heating power or by pulling out the growing crystal carefully from the melt.

This method is especially used to produce sapphire boules with a weight of 100 kg and more. From the sapphire boules substrates are manufactured on which GaN based LEDs are epitaxially deposited on an industrial scale. Also, alkali halide crystals for optical components (NaCl, KBr) and alkali iodides for scintillators (NaI, CsI) are grown by the Kyropoulos technique. Crystals with dimensions over 500 mm have been achieved.

Shaped crystal growth

For a variety of technological applications, crystals of specified size and shape like plates, rods, tubes, fibers are required. Often it is more cost efficient to grow shaped crystals instead of preparing the needed shape from cylindrical boules as they are grown by, e.g., the Cz method.

The diameter of a crystal in the Cz pulling techniques is controlled by the shape and position of the melt meniscus at the triple contour crystal-melt-gas (or encapsulant). This control can be improved by using a die which is in contact to the melt. The melt raises in a narrow channel within the die due to capillary effects. When the seed crystal is dipped onto the melt portion at the top of the die, the meniscus is formed and liquid solidifies at the seed while the seed is pulled away (Fig. 6). This causes new liquid to raise up in the die. The heat of crystallization is removed from the solid-liquid interface very efficiently by conduction and by radiation.

The method for growing shaped crystals as described above is commonly known as Stepanov method (non wetting die-melt system) or Edge-defined Film-fed Growth (EFG) (wetting die-melt system). In the case of fiber crystals the method is also called

Fig. 6 Schematic of the principle of the Edge defined Film fed Growth (EFG) method.

Fig. 7 Schematic of the principle of the μ PD (a), NCS (b), GES (c) methods.

Micro Pulling Down method (μ PD) because a crystal fiber with a diameter of only some hundred microns can be grown from a die by pulling the crystal downwards (Fig. 7a). Variants of the EFG method are the Non-capillary Shaping (NCS) method where the diameter of the die channel is greater than the value of the capillary constant (Fig. 7b). The NCS method offers advantages in order to avoid the generation of bulk micro defects in the growing crystal caused by gaseous or solid inclusions.

Applying a continuous displacement to the growing crystal or the die allows one to grow crystals with more complex shapes (Fig. 7c), like for example domes or hollow cones. This method is named Growth from an Element of Shape (GES).

Nowadays, shaped crystal growth is mainly used for industrial production of sapphire. Sapphire crystals in form of ribbons up to 150 mm in width, tubes up to 85 mm in diameter, fibers, near-net-shaped domes (up to 80 mm in diameter), rods of various cross-sections, rods with capillary channels, etc., are grown by the shaped growth techniques described above (Kurlov (2001), see Fig. 8). For photovoltaic applications thin silicon ribbons or thin wall (octagonal) tubes have been industrially produced by EFG

Fig. 8 Shaped sapphire crystals grown by the EFG, NCS, and GES techniques. From Kurlov VN (2001) Sapphire: Properties, growth, and applications. In: Buschow KHJ, Cahn RW, Flemings MC, Ilshner B, Kramer EJ, Mahajan S, and Veyssi re P (eds.) *Encyclopedia of Materials: Science and Technology*, pp. 8259–8265. Amsterdam: Elsevier/North-Holland.

like methods. But, most of these technologies were stopped due to cost and productivity reasons a few years ago. The EFG technique is nowadays also used for the industrial production of Ga_2O_3 crystals, a novel ultra-wide-band-gap semiconductor material for power electronic and optoelectronic applications.

Directional solidification

Opposite to crystal pulling, the growth of single crystals in directional solidification is achieved by melting a charge in a crucible and controlled freezing of the melt inside this crucible from one end (seed) to the other (tail). Directional solidification is the basic principle of controlled solidification of a melt. It has been used for many materials for a long time and has its origin and greatest importance in the field of metallurgical casting.

Directional solidification has several advantages compared to the Cz methods. It operates usually under stable hydrodynamic conditions, it is well suited for computer modeling and for automatic process control, the crystal solidifies under low thermal stress conditions, cylindrical or square shaped crystals are grown without any diameter control, and the equipment is less expensive.

However, a crucial limitation of directional solidification is that a strong interaction between the growing crystal and the crucible material might occur, resulting in crystal imperfections which limits the yield and hence the industrial applicability. Furthermore, the failures generated in the crystal during growth, e.g., by twinning or polycrystal formation cannot be observed in situ during growth. A correction by re-melting as it is done in the Cz methods is, therefore, not possible.

Gradient freeze and Bridgman-Stockbarger techniques

The crystal growth configuration consists typically of a tube furnace which provides a temperature profile with a negative gradient parallel to the growth direction (Fig. 9). The method can be carried out by moving the growth interface in horizontal or vertical direction. The single-crystal seed is positioned at one end of the horizontal boat or the lower end of the vertical crucible. Then, the crystal is grown by a controlled shifting of the temperature profile relatively to the solid-liquid interface. Three possibilities exist: moving the crucible relatively to the fixed furnace (Bridgman-Stockbarger method); moving the furnace relatively to the fixed crucible; and without any mechanical movement, only by shifting the temperature profile by a controlled change of the heating powers of the furnace (Tamann-Stoeber or Gradient Freeze Method).

Based on one of these principles one calls the technique the horizontal Bridgman (HB) or the vertical Bridgman (VB) or the Vertical Gradient Freeze (VGF) method. From an industrial point of view, the vertical configurations (VGF, VB) are preferred because they result in a higher yield of appropriate shapes of the wafers compared to the HB method.

The increasing interest in the use of directional solidification results from the fact that it uses the simplest principle of melt growth and that the structural perfection of the single crystals with respect to thermal stress and dislocation formation is better than of crystals produced by Cz methods.

Nowadays, the VGF or VB method is mainly used for the production of compound semiconductors like high quality GaAs (Fig. 10) and InP single crystals or CdZnTe crystals for infrared detectors. A variety of oxide and fluoride crystals are grown by VGF/VB methods for high value applications, too. As one example might serve CaF_2 crystals (Fig. 11) utilized as lenses for the deep ultra violet wavelength in the semiconductor lithography technology. In the field of metallurgy, directional solidification is used to grow single crystalline turbine blades made from nickel-based superalloys (Fig. 12).

In the last two decades the directional solidification (DS) method has gained much attention for the industrial production of silicon ingots for photovoltaic applications. The DS method is usually a combination of the classical VB and VGF method (Fig. 13). In this case the crucibles have square cross sections with dimensions of multiple the dimensions of solar cell wafers (today

Fig. 9 Schematic of the principle of directional solidification methods; (a) Vertical Gradient Freeze Method; (b) Vertical Bridgman Method.

156 mm $\times$ 156 mm). Three DS variants are in use. DS without seed crystals resulting in standard "multi-crystalline" ingots (see Fig. 14a), DS with small sized silicon particles at the flat bottom resulting in so-called "high performance multi" silicon ingots (Fig. 14b), and DS with single crystalline seed plates at the flat bottom resulting in "quasi-mono-crystalline" ingots (Fig. 14c). In the past up to 70% of the solar silicon ingots were grown by DS. But, the market share of DS silicon has dropped already and will drop further in favor of Cz silicon because of the potential to achieve a higher solar cell efficiencies at lower production cost than DS.

Today, often an active cooling below the crucible bottom is used during DS of solar silicon to extract the heat more efficiently. Originally, a gas-cooled heat exchanger was applied. Therefore, this special variant of the DS technique is also named Heat Exchanger Method (HEM). HEM was developed mainly for the growth of large sapphire crystals with diameters up to 500 mm. Today, large BGO (Bismuth Germanate) crystals are also grown industrially by HEM in addition to sapphire and silicon.

For refractory materials with high chemical reactivity and melting points above 2000 °C often no suitable crucible material exists. This problem can be overcome by using the Skull Melting technique, where the material to be grown serves as an inner cover of a cooled crucible. Radio-frequency heating is used to melt the charge contained in a water cooled crucible (e.g., copper). As a result of the water cooling, a skull of sintered material is formed and acts as a non-contaminating inner crucible wall for the melt. Crystals are typically grown by directional solidification of the molten charge without a seed crystal. The method is used, for example, to grow several hundreds of tons of cubic ZrO_2 per year for gemstones. Sometimes this technique is also named Cold Crucible Technology especially when the melt is levitated by a RF field in such way that no contact exists between the molten charge and the water cooled crucible.

Fig. 13 Schematic sketch of a DS set-up (right) for the crystallization of mc-Si. The sketched axial temperature profiles (left) are related to different time steps (t_1 , t_2 , t_3) of the process; t_1 affiliates the beginning of crystallization, t_2 and t_3 intermediate steps. T_m denotes the melting temperature. The dashed horizontal lines mark the position of the s-l interface at the corresponding time steps (t_1 , t_2 , t_3). After Müller G and Friedrich J (2010) Optimization and modeling of photovoltaic silicon crystallization processes, 14th international summer school on crystal growth. *AIP Conference Proceedings* 1270: 255–281.

One interesting variant of the directional solidification method is the so-called detached solidification. In detached solidification, which is also called de-wetting growth process, a small gap between the growing crystal and the crucible wall exists. The formation and stability of such a gap depends on the wetting behavior between the melt and the crucible material, the contact angle, the growth angle and external forces (especially a certain gas pressure difference between the gap and the top of the melt). The experimental results achieved so far for CdTe, Ge, GeSi and GaSb on a laboratory scale on earth and also under microgravity conditions demonstrate that the structural perfection of the crystals is generally improved when the de-wetting effect occurred. However, a transfer to industrial production did not take place so far.

Zone melting in crucibles

In zone melting only a part of the solid is molten in a crucible or a boat by using a resistance or RF zone heater; Fig. 15 shows the horizontal arrangement of zone melting. Growth is achieved by moving the heat source relatively to the axis of the container.

Fig. 14 Scan images revealing different grain orientations of vertical cuts (parallel to the growth direction) of silicon crystals grown without seeding (a: standard multi), with polycrystalline silicon particles as seeds (b: high performance multi), and with single crystalline seed (c: quasi-mono). The blue lines mark the seed surface before the melting process. The dotted lines mark the shape and position of the interface at beginning of growth. By courtesy of Fraunhofer IISB, Erlangen.

Fig. 15 Schematic of the principle of zone melting.

Nowadays, the importance of zone melting for bulk crystal growth is mainly limited to its use for purification of the feed material. Impurities with a segregation coefficient $k_0 < 1$ can be accumulated very efficiently by multiple passes of melt zones toward the end of the ingot. Therefore, zone melting is still the industrial standard technology for purification of metals and, e.g., germanium feedstock.

Floating zone (crucible-free zone melting)

The floating zone (FZ) technique is a crucible-free crystal growth method. In FZ growth, the molten zone is kept between two vertical solid rods by its own surface tension (Fig. 16). The FZ process is started by dipping a seed crystal into one end of the molten zone. Then the molten zone is moved toward the feed rod and at the other zone end the crystal is growing.

The main advantage of the FZ technique is the absence of a container which avoids any contamination by the crucible material. Furthermore, the generation of crystal defects caused by an interaction between the growing crystal and the container is avoided. Therefore, the technique is especially useful for growth of highly reactive materials, intermetallic compounds, and refractory materials. The heating of the molten zone can be achieved by several methods including RF, optical, electron beam, laser and resistance heating.

Fig. 16 Schematic principle (left) and photography (right) of the Floating Zone method for growing Si crystals.

The industrial application of the FZ technique is rather limited because the maximum sample diameter is relatively small due to the difficulties to maintain a stable molten zone. Usually the maximum height of the molten zone is only a few mm. It depends mainly on the ratio between the surface tension and the density of the melt.

In the industrial FZ growth of silicon the so-called needle-eye technique is used to stabilize the shape of the molten zone by an electromagnetic pressure field generated with a specially shaped rf-induction coil. This enables the production of silicon crystals with diameters up to 200 mm and extremely low oxygen contamination ($<10^{16} \text{ cm}^{-3}$). Such pure silicon crystals are needed especially for the fabrication of power electronic devices.

Crystals of other materials with higher density and lower surface tension like, e.g., GaAs or GaSb can only be grown with larger diameters under microgravity conditions (Fig. 17).

Verneuil technique

The Verneuil technique (Fig. 18), also called the flame fusion technique, is one of the oldest methods for growing refractory oxide crystals. The feed consists of a fine powder of the crystal material which is transported into the flame of an oxygen-hydrogen burner. The fused particles are falling down on top of the growing crystal and form a thin melt film on top of it. A continuous growth process is achieved by slowly pulling down the crystal. It is important to balance the rate of powder feed and the rate of pulling to maintain a constant growth rate and crystal diameter. Otherwise, the thermal field in the vicinity of the solid-liquid interface is changed which results in poor crystal quality.

The advantage of this process is the low equipment costs. The main disadvantage is the extremely large temperature gradient causing a high density of stress-induced crystal defects. Therefore, often an after heater is used in order to prevent the crystal from cracking.

Nowadays, the Verneuil technique is exploited for the economic mass production of, e.g., sapphire and ruby crystals for jewelry and precision bearings (several hundreds of tons per year). Most high-melting oxide compounds can be grown using this technique.

Solution growth

Growth of a crystal from a solution is an option for cases where melt growth is not possible for reasons like extremely high melting temperature, extremely high vapor pressure, non-congruent melting or destructive structure transformations during cooling of the crystal (e.g., quartz). In solution growth the elements or compounds of the material to be crystallized are dissolved in a suitable solvent. Crystal growth is achieved by supersaturation of the solution and deposition of the crystal material on a seed crystal.

Fig. 17 GaAs crystals grown by the Floating Zone technique; left: sample grown in space under microgravity during the German Spacelab mission D2, right: sample grown on earth with maximum size. By courtesy of Fraunhofer IISB, Erlangen.

Fig. 18 Schematic principle of the Verneuil method.

Principle of solution growth

Firstly a solvent must be found which dissolves the crystal material and is not incorporated into the growing crystal. Then, the solution has to be supersaturated which can be achieved by different means:

- In the temperature changing technique, the solution is supersaturated by slow cooling as the solubility is usually decreasing with decreasing temperature (supersaturation is achieved by slow heating, if the solubility decreases with increased temperature)
- In the evaporation technique, the supersaturation is obtained by controlled evaporating of the solvent at a constant temperature.
- In the temperature gradient technique, two regions of different temperatures T_1 and T_2 ($T_2 < T_1$) are established. In the region with temperature T_1 the feed material is dissolved, while crystal growth takes place in the region with temperature T_2 .

In solution growth, the growth rate is mostly limited by the transport rate of the solute to the growth interface. Therefore, an active mixing, e.g., by stirring and crucible rotation techniques are in use (e.g., Sangwal (2001), see Fig. 19).

An important issue in solution growth is the selection of a suitable solvent. At the growth temperature the solvent should generally have a sufficient solubility of the material to be grown and also a low vapor pressure and a low viscosity.

Low temperature solution growth

Low temperature solution growth is one of the simplest methods to grow single crystals especially if aqueous solutions are used (Fig. 19). Industrially important crystals grown by low temperature solution growth are potassium dihydrogen phosphate (KDP, Fig. 20), ammonium dihydrogen phosphate (ADP), both for electro-optic applications.

High temperature solution growth

Practically any material can be grown by high-temperature solution growth (often also called flux growth). Mainly low melting temperature solvents (fluxes), often molten salts and oxides, are used as solution.

For a variety of technical important materials like $\text{Sr}_{1-x}\text{Ba}_x\text{Nb}_2\text{O}_6$ (SBN), $\text{Pb}_{1-x}\text{Ba}_x\text{Nb}_2\text{O}_6$ (PBN), LiNbO_3 , BaTiO_3 (BTO), BaB_2O_4 (BBO), the so-called Top Seeded Solution Growth method (TSSG) is used (Fig. 21). TSSG corresponds to the Cz method the only difference is that a solution is used instead of the melt.

A special industrial application case for solution growth is the production of CdTe crystals respectively CdZnTe for X-ray detectors. They are grown by the so-called Traveling Heater Method (THM). THM is a variant of zone melting, but the “melt”

Fig. 20 Potassium dihydrogen phosphate (KDP) single crystal grown from aqueous solution. By courtesy of CEA.

Fig. 21 Typical set up for the temperature gradient solution growth technique with top seeding (TSSG).

zone is replaced by a solution (e.g., Te in the case of CdTe). The movement of the “traveling” heater causes the dissolution of the feed at the high temperature end of the zone and growth at the low temperature end. For other semiconductor crystals like SiC or GaN the use of solution growth is limited to research.

The principle of solution growth allows also to grow thin layers epitaxially on substrates. This technique, which is called Liquid Phase Epitaxy (LPE) is used, e.g., for growth of HgCdTe layers on CdZnTe substrates for infrared applications.

In summary one can state that crystals grown from solution have less structural defects than crystals grown from melts due to the lower growth temperature. However, the growth rates are small compared to melt growth techniques and sometimes the solvent contaminates the crystal.

Hydrothermal growth

Hydrothermal growth is a special variant of solution growth from aqueous solution at temperatures above 100 °C. The increased temperatures (up to about 400 °C) are necessary to enhance the solubility of the solute in the aqueous solvent. But this causes an

Fig. 22 Production of quartz crystals in the world's largest autoclave. From Rudolph P (2015) *Handbook of Crystal Growth*, Vol. II, 2nd ed., Amsterdam: Elsevier/North-Holland.

extremely high pressure (several kbars) of the supercritical aqueous solvent. The growth process includes typically heterogeneous reactions and is supported by mineralizers. A precisely controlled temperature gradient is used to achieve the crystallization at the seed location (principle c in section “[Principle of solution growth](#)”).

The most important application of the hydrothermal method is the industrial growth of synthetic quartz (SiO_2) crystals (Fig. 22). It is carried out in special vessels called autoclave or bomb under pressures of typically 170 MPa and temperatures around 400 °C. This technique is also used in industry to grow berlinite (AlPO_4), calcite (CaCO_3), gallium phosphate (GaPO_4), triglycine sulfate (TGS) and zincite (ZnO) crystals. In addition, another variant of the hydrothermal method, called “ammono”-thermal method, was developed which uses supercritical ammonia (instead of water). GaN bulk crystals are grown by this ammono method even on an industrial scale. Also other nitrides can be synthesized by this technique.

Growth under extreme high pressure

High pressure synthesis refers to the growth of diamond crystals. Diamond can be grown from graphite at a temperature around 1300–1500 °C under a pressure of around 60 kbar. These conditions are provided by a set up with special anvils generating the high pressure in the heated growth cell. The growth cell contains graphite mixed with a metal or alloy that serves as a solvent/catalyst. At around 1300–1500 °C diamond is the stable modification whereas graphite becomes meta-stable and is partially dissolved in the solvent. The solubility difference acts as driving force for the conversion of carbon from graphite to diamond crystals.

Vapor growth

Vapor growth is like solution growth usually applied when melt growth is impractical. Due to the lower temperatures as compared to melt growth, many thermally activated processes like impurity incorporation, compositional uniformity, structural imperfection,

are usually decelerated. Therefore, the crystal quality can be enhanced. However, in vapor growth the growth rates are usually also considerably decreased due to the small density of crystal material in the gas-phase, the low transport rate in the vapor to the growth interface and the decreased interface kinetics with decreasing temperature. It is therefore mainly used in cases where melt and solution growth are not applicable or has severe disadvantages.

Sublimation technique (physical vapor transport)

In physical vapor transport (PVT) often called as sublimation growth, a source material held at a temperature T_1 sublimates, and its vapor is transported by diffusion and convection to the seed crystal held at a lower temperature T_2 where it can crystallize. The supersaturation at the crystallization front depends on the difference of the partial pressures of the sublimated material in the source and equilibrium pressure in the growth region as well as on the total vapor pressure in the system. The supersaturation has to be precisely controlled in order to avoid parasitic nucleation.

The sublimation technique is industrially used to produce silicon carbide crystals (Fig. 23) with diameters of up to 150 mm and even 200 mm for electronic applications. The growth takes place in an inductively heated graphite crucible at elevated temperatures (2100–2400 °C). The transport of gaseous Si, Si_2C and SiC_2 species is established from the SiC source to the growing SiC single crystal in an Argon atmosphere (10–100 mbar).

Also aluminum nitride (Fig. 24) is grown in industry by the PVT method at temperatures far above 2000 °C. The PVT method is also used for II-VI compounds.

Chemical vapor transport and chemical vapor deposition

In the crystal growth methods by chemical vapor transport (CVT) or deposition (CVD), respectively, a reactive gas is used which reacts with the source material or gaseous chemical compounds (called precursor) containing the crystal components. These chemical species containing the source material are transported in the gas phase to the growth zone of a reactor. Here, the reactions take place by forming the crystal components which are then deposited at the growth interface.

Both methods CVT/CVD have nearly no importance in bulk crystal growth. Only thick free-standing gallium nitride wafers, respectively gallium nitride boules (Fig. 25) are presently grown by a hydride CVD called HVPE (Hydride Vapor Phase Epitaxy).

But CVD is the dominant industrial method for producing thin films including epitaxially grown layers, especially by using metal organic precursors, called metal organic vapor deposition MOCVD.

Conclusion

Bulk growth of inorganic crystals is an important industrial key technology. Fig. 26 gives an overview about the development of the annually produced wafer area of different semiconductor crystals and sapphire based on the data of different market surveys.

The mainly industrially used crystal materials are grown by solidification of their melt like Si, sapphire, GaAs, InP, Ge, CZT. Only a few materials are grown from solution or vapor phase. This is true especially for the class of wide band gap semiconductor materials like SiC, GaN, AlN and Diamond.

The growth techniques are well established and suitable to grow in principle any inorganic crystal material. Nevertheless continuous R&D efforts are still necessary for a further development of the crystal growth processes to fulfill the demands on special crystal properties coming from the various fields of applications. Among the most important R&D tasks are

Fig. 26 Development of the annually produced wafer area of different semiconductor crystals (Si, Ge, GaAs, InP, SiC, GaN, CdZnTe (CZT), Diamond) and sapphire based on the data of different market surveys (<http://www.yole.fr>, <https://ihsmarkit.com>). In case of silicon only silicon for electronics is considered, but not silicon for photovoltaics. By courtesy of Fraunhofer IISB, Erlangen.

- avoiding of crystal defects which are deleterious for the performance of devices made from the crystals,
- better control of crucial processing parameters in order to tailor the physico-chemical properties of the crystals according to the needs of their applications,
- an increased uniformity of the relevant crystal properties in the micro- and macro-scale and finally
- up-scaling of the growth systems in order to grow crystals of larger dimension for higher productivity and yield.

Abstract

We discuss in general terms the models that are appropriate for describing interatomic forces and performing atomistic simulations in ionic materials. In particular we show how the framework of density functional theory (DFT) and second-order perturbation theory provides a unified way of deriving ionic models, including the Born model and shell models, besides variable charge-transfer models, such as charge equilibration models, and the self-consistent tight-binding model. We also discuss progress in the direct numerical fitting of functions to calculated data, which has made significant progress in recent years with the development of machine learning interatomic potentials and other data-driven approaches.

Key points

- Models of bonding and interatomic forces in ionic materials
- Explanation of most classes of model by deriving them from density-functional theory (DFT)
- Examples from rigid-ion models to deformable ion models and charge-transfer models
- Brief introduction to machine-learning approaches

Introduction

We can distinguish the models of ionic materials by their increasing degrees of sophistication, which are described briefly below. All contain parameters of one sort or another that have to be fitted either to experimental data or to the data from best available calculations. These are usually calculations using Kohn–Sham density functional theory (DFT), which has proved to be a reliable method in very many cases, especially if the system only involves light and nonmagnetic elements. To provide data of so-called chemical accuracy (better than 1 meV/atom) and to deal with the more difficult elements, higher quality first-principles methods are required, which are much more computationally expensive, and impractical for the routine generation of large quantities of data. Following this introduction, there is a more detailed discussion of how ionic models in general can all be related to DFT within second-order perturbation theory.

The simplest ionic model is the *rigid ion model*. It is sometimes called the *Born model* after its pioneer Max Born and his coworkers in Edinburgh, who over 50 years ago developed most of the mathematical description of the ionic model that we still use; see for example the book by [Born and Huang \(1954\)](#). Within the context of density functional perturbation theory, we can think of it as a first-order model, as we shall see in the following section. The ions interact by the Coulomb interaction, in addition to which there is a short-range pairwise repulsion.

Ions are not rigid, and the *shell model* was first developed by [Dick and Overhauser \(1958\)](#) to include their polarizability. In its simplest version, a spherical shell of charge $-q^s$ surrounds an ion of reduced charge $\Delta Z + q^s$ and is attached to it by a harmonic spring. The nominal ionic charge is ΔZ . The repulsion between ions is now modeled as a repulsion between the centers of these shells.

The *compressible ion model* is an extension of the shell model in which the radius of the shells is a variable. The energy of a compressible ion is a function of this radius, which adjusts according to the environment of the ion. This model is most strongly

motivated by the case of oxygen, as discussed further below. The traditional models were mainly constructed by fitting their parameters to experimental data. This provides a disincentive to making them too sophisticated since the number of parameters would become so large that they could fit anything without any guarantee of being physically sound. The compressible ion model was held back for this reason, since in its early days, the parameters were determined by fitting them to experimental phonon dispersion curves. The work of Madden, Wilson, Pyper, and others (see for example, [Wilson et al., 1996](#) and references therein) attempted to reduce the empirical nature of the parameters by fitting them individually, rather than altogether. They were fitted to total energy data obtained by first-principles calculation on molecules and crystals at chosen interatomic distances. This approach also made it feasible to introduce independent parameters to describe quadrupolar polarization. Further developments of the polarizable ion approach include the fitting of model parameters to a large number of forces as a function of atomic configurations ([Tangney and Scandolo, 2002](#)). This approach, which uses the data generated by molecular dynamics performed with a density-functional code, is discussed further below. Even so, the most sophisticated ionic models take no explicit account of covalent effects, and this may be a significant shortcoming.

None of the aforementioned ionic models allow for the fact that the charge associated with an ion also depends on its environment. This has been treated in an empirical way by the model introduced by [Streitz and Mintmire \(1994\)](#). A more recent approach is to use self-consistent tight binding, which in principle can be regarded as an ionic model with a degree of covalency included, as described in [Finnis \(2003a\)](#). Covalency is represented in the tight-binding model by the nonvanishing elements of a Hamiltonian matrix linking atomic-like orbitals. In fact most other models can be derived from a tight-binding description by making specific approximations, perhaps the most drastic being the complete neglect of interatomic Hamiltonian matrix elements as in the variable charge transfer, or charge equilibration model, or the neglect of *all* covalent effects, as in the rigid ion model.

This article is an update of the original, which was entirely based on Chapter 9 of the book by [Finnis \(2003a\)](#). We focus here on key methodological developments rather than aiming to provide a comprehensive review of applications; for the latter, see for example, [Pedone et al. \(2022\)](#). Since [Finnis \(2003b\)](#) was published, a key trend in the construction of interatomic potentials has been the increased use of data-driven and machine learning techniques to automatically construct nonparametric models from reference data, typically at the DFT level. Initially such approaches were mainly applied to covalent materials where interactions are short-ranged, but recently they are seeing increased adoption also for ionic systems.

The rigid ion model

To derive ionic models, like other models, we start with an input charge density $\rho^{\text{in}}(\mathbf{r})$. It is constructed, at least notionally, by superimposing spherical “atomic” charge densities. The atomic charge density in the sense used here is not necessarily the same as the charge density of free atoms. A judicious choice of atomic charge density could make the input charge ρ^{in} closer to the exact, self-consistent charge density ρ^{ex} , improving the accuracy of a first-order model. The usual picture of the charge in an ionic crystal is of course a superposition of *ions* rather than of atoms, and we might expect that these would be a better starting point. Whether ionic or atomic-like charge densities are superimposed, the variational principle tells us that the error we make in the energy is only second order in the error we make in the charge density, provided that the energy is formulated as a functional of the charge density.

A neat general recipe for the “atomic charge density” is to take the electron density of the nearest noble gas in the same row of the periodic table (see [Fig. 1](#) and [Harrison, 1980](#)). Thus oxygen, fluorine, sodium, magnesium, and aluminum would all be represented by the charge density of neon atoms, chlorine and potassium by argon, and so forth.

This leads us to construct a first-order model for the total energy as follows: First, superimpose the noble gas atoms at the positions required in the material, keeping their charge densities rigid. Let us denote the superimposed charge density by $\rho_{\text{ng}}^{\text{in}}$, where the individual noble gas atom on site I has a density ρ_{ng}^I . Thus

$$\rho_{\text{ng}}^{\text{in}}(\mathbf{r}) = \sum_I \rho_{\text{ng}}^I(\mathbf{r} - \mathbf{R}_I). \quad (1)$$

Let us denote by $E^{\text{HKS}}[\rho_{\text{ng}}^{\text{in}}, V_{\text{ext}}]$ the first-order energy of this system, where

$$E^{\text{HKS}}[\rho_{\text{ng}}^{\text{in}}, V_{\text{ext}}] = T_s[\rho_{\text{ng}}^{\text{in}}] + \int \rho_{\text{ng}}^{\text{in}}(\mathbf{r}) V_{\text{ext}}(\mathbf{r}) d\mathbf{r} + E_{\text{xc}}[\rho_{\text{ng}}^{\text{in}}] - \int \rho_{\text{ng}}^{\text{in}}(\mathbf{r}) V_{\text{xc}}^{\text{in}}(\mathbf{r}) d\mathbf{r} + E_{\text{ZZ}}. \quad (2)$$

The notation introduced here is as follows: E^{HKS} is a density functional that describes the total energy ([Hohenberg and Kohn, 1964](#); [Kohn and Sham, 1965](#)); $T_s[\rho]$ is the kinetic energy of noninteracting electrons with density ρ , V_{ext} is the potential felt by the electrons from the atomic nuclei, $E_{\text{xc}}[\rho]$ is the exchange and correlation energy of the electrons with density ρ , $V_{\text{xc}}^{\text{in}}$ is the exchange and correlation potential, and E_{ZZ} is the nucleus–nucleus Coulomb repulsion. The energy of this system is strongly repulsive because the equilibrium spacing of noble gas atoms is considerably larger than that of the cations and anions in ionic materials. Indeed, because we are dealing with closed shell atoms, we expect the first-order charge density and energy to be rather good approximations to the exact, self-consistent quantities we denote ρ_{ng} and E_{ng} . We now “switch on” the integer charge differences ΔZ_I on the nuclei which

			1 H	2 He	3 Li	4 Be	5 B	6 C			
	7 N	8 O	9 F	10 Ne	11 Na	12 Mg	13 Al	14 Si			
	15 P	16 S	17 Cl	18 Ar	19 K	20 Ca	21 Sc	22 Ti	23 V	24 Cr	
	33 As	34 Se	35 Br	36 Kr	37 Rb	38 Sr	39 Y	40 Zr	41 Nb	42 Mo	
	51 Sb	52 Te	53 I	54 Xe	55 Cs	56 Ba	57 La	58 Ce	59 Pr	60 Nd	
	83 Bi	84 Po	85 At	86 Rn	87 Fr	88 Ra	89 Ac	90 Th	91 Pa	92 U	

Fig. 1 The periodic table centered on the noble gases.

are required to create the nuclei of the actual cations and anions. We regard this as a perturbing external potential to the electrons, given by

$$\Delta V_{\text{ext}}(\mathbf{r}) = - \sum_I \frac{\Delta Z_I}{|\mathbf{r} - \mathbf{R}_I|}. \quad (3)$$

To first order this does not disturb the charge density but it introduces a strong electrostatic cohesive energy, due to the attraction between the unlike charges, which, because of their alternating arrangement in space, more than compensates for the repulsion of like charges. We'll now examine how this works. The total change in the electrostatic interactions of the nuclei introduced by our "transmutation" is

$$\Delta E_{ZZ} = \sum_{I \neq J} \frac{Z_I \Delta Z_J}{|\mathbf{R}_I - \mathbf{R}_J|} + \frac{1}{2} \sum_{I \neq J} \frac{\Delta Z_I \Delta Z_J}{|\mathbf{R}_I - \mathbf{R}_J|}. \quad (4)$$

The second term is called the total *Madelung energy* of the particular structure, and we denote it here as $N_a E_M$, where N_a is the total number of atoms and E_M is the Madelung energy per atom:

$$E_M = \frac{1}{2N_a} \sum_{I \neq J} \frac{\Delta Z_I \Delta Z_J}{|\mathbf{R}_I - \mathbf{R}_J|}. \quad (5)$$

Let us consider in more detail the example of a simple binary crystal structure, in which a formula unit consists of n^C cations of charge ΔZ^C and n^A anions of charge ΔZ^A . These charges derived according to the above definition are sometimes called *formal* charges, to distinguish them from actual electronic charge transfers. Generally, for any material, summing over all sites, charge neutrality requires that

$$\sum_I \Delta Z_I = 0. \quad (6)$$

For our binary crystal, the charge neutrality condition holds for each formula unit

$$n^C \Delta Z^C + n^A \Delta Z^A = 0. \quad (7)$$

Table 1 Madelung constants for ionic crystals, after Johnson and Templeton (1961).

Structure	α_M
NaCl	1.75
CsCl	1.76
α -Al ₂ O ₃	1.68
V ₂ O ₅	1.49

In this case the Madelung energy per atom can be written as

$$E_M = \alpha_M \frac{\Delta Z^C \Delta Z^A}{2R_{CA}}, \quad (8)$$

where R_{CA} is the nearest-neighbor cation–anion distance and α_M is the Madelung constant, which is tabulated in the literature for a number of crystal structures, for example, Johnson and Templeton (1961) and Ashcroft and Mermin (1976, Table 20.4). Examples are given in Table 1. For an arbitrary arrangement of ions, for example, within a supercell, which may comprise thousands of atoms, or without periodic boundary conditions, there are special strategies for calculating $N_a E_M$, such as the Ewald method for periodic systems, which are well described in the textbooks, for example, Ziman (1972, p. 39). Our first-order model for the total energy omits the second-order effects, which arise from the deviation of both ρ_{ng} and of the final exact charge density ρ^{ex} from ρ_{ng}^{in} :

$$\begin{aligned} E^{(1)} &= E^{HKS}[\rho_{ng}^{in}, V_{ext}] + \int \rho_{ng}^{in}(\mathbf{r}) \Delta V_{ext}(\mathbf{r}) d\mathbf{r} + \Delta E_{ZZ} \\ &= E^{HKS}[\rho_{ng}^{in}, V_{ext}] + N_a E_M - \sum_{I \neq J} \int \rho_{ng}^I(\mathbf{r} - \mathbf{R}_I) \frac{\Delta Z_J}{|\mathbf{r} - \mathbf{R}_J|} d\mathbf{r} \\ &\quad + \sum_{I \neq J} \frac{Z_I \Delta Z_J}{|\mathbf{R}_I - \mathbf{R}_J|} - \sum_I \int \rho_{ng}^I(\mathbf{r} - \mathbf{R}_I) \frac{\Delta Z_I}{|\mathbf{r} - \mathbf{R}_I|} d\mathbf{r}. \end{aligned} \quad (9)$$

The interaction of the atomic charge density with the perturbation on its own site has been separated out as the final term. This expression is dominated by the first two terms, namely, $E^{HKS}[\rho_{ng}^{in}, V_{ext}]$ and the Madelung energy. It is a reasonable approximation to write $E^{HKS}[\rho_{ng}^{in}, V_{ext}]$ as a sum of pairwise interactions V_{IJ} since we are dealing with closed-shell atoms. With this assumption we obtain the simplest form of the rigid ion model

$$E_{rim} = \frac{1}{2} \sum_{I \neq J} V_{IJ} + N_a E_M. \quad (10)$$

The remaining first-order terms will be much smaller, as discussed in Finnis (2003a). Now compare these terms with the pairwise electrostatic contributions to $E^{HKS}[\rho_{ng}^{in}, V_{ext}]$:

$$\iint \frac{\rho_{ng}^I(\mathbf{r}) \rho_{ng}^J(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r} d\mathbf{r}' + \frac{Z_I Z_J}{R_{IJ}} - \int \left\{ \frac{\rho_{ng}^I(\mathbf{r}) Z_J}{|\mathbf{r} - \mathbf{R}_J|} + \frac{\rho_{ng}^J(\mathbf{r}) Z_I}{|\mathbf{r} - \mathbf{R}_I|} \right\} d\mathbf{r}. \quad (11)$$

This interaction will generally be much bigger. Notice that it involves the full nuclear charges Z rather than ΔZ ; second, it is always repulsive, because it comprises the direct Coulomb interaction between nuclei partially screened by the electron distributions; and third, it is of longer range, being nonzero when ρ_{ng}^I overlaps ρ_{ng}^J , not merely Z_J . The terms we are considering are all strictly pairwise, and so can be exactly accounted for by a relatively small correction to the V_{IJ} we have introduced to represent $E^{HKS}[\rho_{ng}^{in}, V_{ext}]$. Since the form of V_{IJ} in practical applications has been parameterized, the extra terms could be absorbed without explicitly evaluating them.

Let us now return to the rigid ion model in the form (10) and consider its virtues, the chief of which is simplicity, and its shortcomings, which can be defined in terms of polarization of the ions and covalency. It was first derived on the basis of overlapping noble gas atomic charge densities by Gordon and Kim (1972) and Kim and Gordon (1974). They used a completely local DFT (including the local kinetic energy functional) to evaluate the pair potential between noble gas atoms, with atomic charge densities overlapped but unrelaxed, and they discovered that this could account fairly well for the lattice parameters and bulk moduli of ionic crystals. Their $E^{HKS}[\rho_{ng}^{in}, V_{ext}]$ could also be fairly well fitted by the Lennard-Jones potential (Gordon and Kim, 1972), the parameters of which we have used, together with the appropriate Madelung energy, to calculate bond lengths in a number of compounds, as illustrated in Fig. 2, where the results are compared with experimental bond lengths. Because some of the crystal structures are a bit complicated, we have made convenient simplifications so that the bond length can be predicted by minimizing the energy analytically with respect to R_{CA} . For example, we have only included nearest neighbor interactions in the Lennard-Jones potential. Then for Al₂O₃, we took as the “experimental” bond length the sum of ionic radii for Al³⁺ and O²⁻, namely, 0.191 nm (Kittel, 1976), which is also the mean of the two close neighbor bond lengths observed in the actual corundum structure. Such ionic radii incidentally reproduce the experimental bond lengths of the other common oxides to an accuracy of 0.002 nm. Notice that in some cases a mixture of rare gases is involved, for example, Nb₂O₅ has to be built out of Kr and Ne because Nb in the 5+ state of ionization resembles Kr. Since a value for the Madelung constant was not listed in this case by Johnson and Templeton,

Fig. 2 Bond lengths calculated from Lennard-Jones and Madelung energies.

we assumed their V_2O_5 value would do for Nb_2O_5 . The agreement of calculated and observed bond lengths in such diverse materials as ZrO_2 and KCl , with no fitting of parameters to any experimental data, is quite striking. Not surprisingly the worst candidate tested here is SiC , which is a classic covalent compound, but even in this case the crude ionic model does better than we might have expected since the perturbations ΔZ_i are by no means small. Such is the power of the variational principle. We should add that the relatively good agreement of this model breaks down when it comes to calculating the second derivative of the energy, the bulk modulus. Superficially, that is easily repaired if one allows the pair potential to be empirically fitted. Predictions of phonon frequencies and the properties of defects nevertheless generally require a higher quality model than rigid ions can provide even when some degree of empirical fitting is allowed.

Beyond the rigid ion model

The basic second-order model

Several other models can be derived within the broad framework of a second-order functional, which can be written in terms of the reference density from the noble gas atoms as

$$E^{(2)}[\rho] = E^{\text{HKS}}[\rho_{\text{ng}}^{\text{in}}, V_{\text{ext}}] + \int \rho_{\text{ng}}^{\text{in}}(\mathbf{r}) \Delta V_{\text{ext}}(\mathbf{r}) d\mathbf{r} + \Delta E_{\text{ZZ}} + \int [\rho(\mathbf{r}) - \rho_{\text{ng}}^{\text{in}}(\mathbf{r})] \Delta V_{\text{ext}}(\mathbf{r}) d\mathbf{r} - \frac{1}{2} \int \int [\rho(\mathbf{r}) - \rho_{\text{ng}}^{\text{in}}(\mathbf{r})] \chi_{e1}^{-1}(\mathbf{r}, \mathbf{r}') [\rho(\mathbf{r}') - \rho_{\text{ng}}^{\text{in}}(\mathbf{r}')] d\mathbf{r} d\mathbf{r}'. \quad (12)$$

The linear response function $\chi_{e1}(\mathbf{r}, \mathbf{r}')$, of which the inverse operator $\chi_{e1}^{-1}(\mathbf{r}, \mathbf{r}')$ appears here, measures the density induced at $\mathbf{r}$ by a delta function of external potential at $\mathbf{r}'$. Recall that the first term represents the energy of the noble gas solid to first order, and the idea is that the above rigid ion model has taken care of this and the next two terms, that is all terms of first order in ΔV_{ext} . The task is then to approximate the two remaining terms that depend on $[\rho - \rho_{\text{ng}}^{\text{in}}]$ and that are both of second order in ΔV_{ext} . The second-order energy functional in this picture is therefore

$$E^{(2)}[\rho] = \frac{1}{2} \sum_{I \neq J} V_{IJ} + N_a E_M + \int [\rho(\mathbf{r}) - \rho_{\text{ng}}^{\text{in}}(\mathbf{r})] \Delta V_{\text{ext}}(\mathbf{r}) d\mathbf{r} - \frac{1}{2} \int \int [\rho(\mathbf{r}) - \rho_{\text{ng}}^{\text{in}}(\mathbf{r})] \chi_{e1}^{-1}(\mathbf{r}, \mathbf{r}') [\rho(\mathbf{r}') - \rho_{\text{ng}}^{\text{in}}(\mathbf{r}')] d\mathbf{r} d\mathbf{r}'. \quad (13)$$

The difference between this second-order functional and a general second-order functional is that the one-electron energies are here subsumed into the classical pairwise potential, an approximation that is only at all justified by the closed-shell electronic structure of noble gas atoms. By this maneuver, we have shifted the entire responsibility for the description of any covalent bonding effects, which are of second order in $[\rho - \rho_{\text{ng}}^{\text{in}}]$, onto χ_{e1} . The response function χ_{e1} refers to an electron density distribution $\rho_{\text{ng}}^{\text{in}}$ and we can only model it in rather crude ways. Whatever way we do this, and an example is given below, the model so generated is entirely classical in form, and requires $E^{(2)}[\rho]$ to be minimized directly with respect to ρ , without the solution of any Schrödinger equation. The resulting density will then satisfy

$$\rho(\mathbf{r}) - \rho_{\text{ng}}^{\text{in}}(\mathbf{r}) = \int \chi_{e1}(\mathbf{r}, \mathbf{r}') \Delta V_{\text{ext}}(\mathbf{r}') d\mathbf{r}'. \quad (14)$$

Modeling deformable ions

The above formalism is a way to derive the shell model, and its many variations, in order to extend the rigid ion model to introduce deformable ions. Originally this model was entirely empirical, providing sufficient disposable parameters to fit phonon spectra much better than previous models. Now from the previous analysis, we are in a better position to see how its parameters can be related to real physical quantities. The shell model is in effect a representation of the terms in $\rho - \rho_{\text{ng}}^{\text{in}}$:

$$\begin{aligned} \Delta E^{(2)}[\rho] &= \int [\rho(\mathbf{r}) - \rho_{\text{ng}}^{\text{in}}(\mathbf{r})] \Delta V_{\text{ext}}(\mathbf{r}) d\mathbf{r} \\ &\quad - \frac{1}{2} \int \int [\rho(\mathbf{r}) - \rho_{\text{ng}}^{\text{in}}(\mathbf{r})] \chi_{e1}^{-1}(\mathbf{r}, \mathbf{r}') [\rho(\mathbf{r}') - \rho_{\text{ng}}^{\text{in}}(\mathbf{r}')] d\mathbf{r} d\mathbf{r}'. \end{aligned} \quad (15)$$

In this case the density $\rho - \rho_{\text{ng}}^{\text{in}}$ of Eq. (13) is modeled by the sum of displacements by $\mathbf{u}_i^s$ of rigid, spherical shells of negative charge $-\Delta q_i^s$ originally centered about each atom. Each shell is tethered to its nucleus by a spring. At equilibrium in a perfect crystal an undisturbed shell can be thought of as representing part of the density $\rho_{\text{ng}}^{\text{in}}$. The shells are assumed to be massless since the inertia of electrons does not enter the dynamics of the system in the Born–Oppenheimer approximation, which is the framework for all the models. When the atoms are not in their equilibrium positions, the shells are subject to three kinds of forces, corresponding to three terms in the total energy. First, they are pulled toward their nuclei by the tethering spring; second, they are pulled toward other nuclei by the Coulomb attraction; and third, the shells repel each other. The first two kinds of forces are a representation of the term $\int (\rho - \rho_{\text{ng}}^{\text{in}}) \Delta V_{\text{ext}}$ in Eq. (13). In the harmonic approximation, the change in energy when the shells are displaced by $\mathbf{u}_i^s$ from their nuclei has the form

$$\begin{aligned} \Delta E^{(2)} &= \frac{1}{2} k u_i^{s2} + \sum_{j \neq i} \left\{ -q_i^s \Delta Z_j \left[\frac{1}{|\mathbf{R}_i + \mathbf{u}_i^s - \mathbf{R}_j|} - \frac{1}{|\mathbf{R}_i - \mathbf{R}_j|} \right] \right. \\ &\quad \left. + \frac{1}{2} q_i^s q_j^s \left[\frac{1}{|\mathbf{R}_i + \mathbf{u}_i^s - \mathbf{R}_j - \mathbf{u}_j^s|} - \frac{1}{|\mathbf{R}_i - \mathbf{R}_j|} \right] \right\}. \end{aligned} \quad (16)$$

A number of points can be made about this model. First, it captures the long-ranged Coulomb interactions between induced dipoles. The on-site elements of χ_{e1}^{-1} are represented within the first term $\frac{1}{2} k u_i^{s2}$ while the last term in the braces represents its intersite elements. The Coulomb interactions in (16) could be expanded to first order in $\mathbf{u}_i^s$ to display the dipole–dipole interactions explicitly, and indeed the model could be formulated in terms of variable dipoles on the sites instead of explicit shell charges and displacements. These Coulomb interactions are an important part of the inverse response function we are trying to model. However, they are certainly not the whole story since the true inverse response function contains terms in the kinetic energy and the exchange and correlation energy. A short-ranged empirical potential between the IIs can be introduced to model these contributions.

In a more realistic model, the shells should be allowed to change their radius in response to their environment. Such an effect might be accomplished by including a kind of compressibility of the ion as a further parameter, which adds a functional dependence on $(r^s - r_0^s)$ to the potential energy, where r^s and r_0^s are the current and relaxed values of the shell radius. This was the idea behind the “breathing shell” model, and subsequently the “compressible ion” model, see for example Marks et al. (2001) and references therein. The compressibility of an ion has a significant effect on properties, and is most noticeable in the case of oxygen because the size of the O^{2-} ion is particularly sensitive to its environment. Indeed, in free space the O^{2-} ion is unstable, which can be thought of as the limiting case of the radius of the ion going to infinity as its coordination is reduced to zero. A noteworthy example of the importance of compressible oxygen is one of the simplest of ionic oxides, MgO. Within the rigid ion model, the Cauchy relation between elastic constants, $C_{12} = C_{44}$, holds since the potential energy is purely pairwise, yet experimentally C_{12} and C_{44} differ by more than 50%. The shell model does not help here because by symmetry, the elastic strains do not displace the shells from their lattice sites, and the Cauchy relation still holds. The difference between C_{12} and C_{44} is only obtained when compressible oxygen ions are introduced. This is because the elastic constant C_{12} is associated with a change in volume, which induces compression or expansion of the ions if the model allows them this degree of freedom. It may help to appreciate this if you think of C_{12} as a linear combination of the bulk modulus $B = \frac{1}{3}(C_{11} + 2C_{12})$ and the shear modulus $C' = \frac{1}{2}(C_{11} - C_{12})$, that is, $C_{12} = \frac{1}{3}(3B - 2C')$.

There are now more sophisticated models with polarizable ions, going beyond the notion of spherical shells and harmonic springs. Closer in spirit to the density functional framework is the approach of Ivanov and Maksimov (1996). These authors represent $(\rho - \rho_{\text{ng}}^{\text{in}})$ as a superposition of atomic charge densities $\rho_{\text{ng},i}^I$, each of which is allowed to shift rigidly with respect to its nucleus, thereby modeling the dipole moments. They calculated the associated changes in energy with a completely local density functional along the lines of Gordon and Kim (1972). A natural extension also considered by Ivanov and Maksimov is to include parameters that describe distortions of the atomic charge densities, such as expansion and contraction or quadrupolar distortion. Besides the local density approximations for kinetic, exchange, and correlation energies, the only limitation of this approach is the number of free parameters one is prepared to include to characterize the charge density.

Another line of attack starts as before with the assumption that the ions are polarizable as dipoles and quadrupoles, and that they are compressible. The strategy is then as far as possible to obtain the many parameters such a model requires as independently as possible, by fitting functions to an extensive set of first-principles calculations on ions in specially chosen potential wells or in

clusters. It is a great improvement on the simple shell model, and can reproduce a range of strain energy data and phonon spectra. However, in spite of the extensive use of first-principles calculations, it is impossible to eliminate some arbitrary choices regarding the functional forms used, and some pairwise approximations. A detailed example of this approach is given by Marks et al. (2001).

Tangney and Scandolo (TS) extended the polarizable ion approach using the “force matching” idea of Ercolessi and Adams (1994) to determine the potential parameters which best reproduce the DFT energies, forces, and stresses on a database of reference configurations. The approach has been applied to a range of oxides including SiO_2 (Tangney and Scandolo, 2002), TiO_2 (Han et al., 2010), and Al_2O_3 (Sarsam et al., 2013). Reformulations of the TS potential to replace the long-range Coulomb interactions with either Yukawa truncation (Kermode et al., 2010) or Wolf summation (Brommer et al., 2010) dramatically reduces the computational cost with negligible loss of accuracy because of physical screening processes which limit the true interaction range.

Variable charge transfer models

In the models described so far in this article, a fixed charge transfer between ions is defined. The net charges on ions are fixed at the formal charges, which are specified by the electronic structure of noble gases. In reality, the occupancy of atomic orbitals varies with the local atomic environment, so it is worth thinking about how this effect can be modeled. In fact a model of ionic crystals that includes covalency, polarisable ions (dipoles and quadrupoles), and variable charge transfer was introduced by Finnis et al. (1998) under the heading of self-consistent tight binding. Self-consistent tight binding offers a way to treat pure metal atoms as well as their oxides since, at least for *sd*-bonded metals, it models the nature of chemical bonding from the metallic to the ionic state.

Conceptually the application of self-consistent tight binding to an ionic material is no different to its application to metals. However, an alternative input charge density might be considered. In the tight-binding models discussed previously, atomic charge densities were superimposed to create the notional input charge density so that all the long-ranged electrostatic interactions appeared in the second-order term. However, one could also formulate the tight-binding model starting from the superimposed atomic charge densities of noble gases, in which case the Coulomb interactions would appear in the pair potential, exactly as they do in the rigid ion model. A systematic study of the consequences of one or the other starting point has not yet been made.

In spite of advantages of self-consistent tight binding in comparison to the models introduced earlier in this chapter, it has certain disadvantages that should be mentioned. These include the obvious one of greater computation time, but there may be others. For example, in current implementations the second-order term is represented by Coulomb interactions between point multipoles. This appears to take no account of the effect that the *compressible ion model* is trying to capture. The logical way to describe a compressible oxygen ion within tight binding would be to include more orbitals of *s* and *p* characters in the basis set so that the spread of the charge density on an anion could vary by transfer of electrons between the orbitals on a site. The price to pay would be more parameters to determine and more computation time. The benefits over a first-principles tight-binding method would be diminished or eliminated.

On the other hand, notions of compressible ions and charge transfer are not absolute; a transfer of electrons from cations to anions might be rather well described in terms of the charge density by a contraction of anion densities accompanied by an expansion of cation charge densities, and vice versa. The tight-binding model predicts a violation of the Cauchy relations because of its noncentral forces and covalency, and possibly charge transfer, whereas the compressible ion model predicts the Cauchy violation from the form of its classical nonpairwise potential energy. A one-to-one mapping of these properties such as charge transfer between the compressible ion model and the tight-binding model is not unique, so it would be unfair to dismiss one or the other description as wrong; they may both be grasping at the same physics from different points of view.

The classical variable charge model (13) is also the basis of an empirical model that includes charge transfers (Streitz and Mintmire, 1994). These authors considered the determination of ρ as a variational problem for which the solution equalizes a classical chemical potential of the electrons everywhere. The result is a model that has some similarities to that of Ivanov and Maksimov (1996). We can think of it as a second-order ionic model with charge transfer, or as a tight-binding model in which the effect of covalency (intersite matrix elements of the Hamiltonian) is neglected. It is a model which enables large-scale molecular dynamics simulations to be carried out, giving a broad-brush description that may be adequate if details such as the relative energies of different structures are not of interest. A prominent example of an empirical variable charge framework, which has been widely applied to ionic materials, is the ReaxFF reactive force field of van Duin et al. (2001); however, due to the large number of terms, parametrization of these models for multicomponent-systems remains challenging.

Machine-learned potentials

In the 2020s, we are witnessing a gradual paradigm shift in the use of DFT calculations, from fitting simple physical models of interatomic potentials, including empirical tight-binding models, to fitting models with the help of machine-learning algorithms. The aim as always is to simulate very large systems and perform the sampling required to obtain dynamic and thermodynamic properties at high temperature, but the ambition has become higher: we now want to retain the accuracy of DFT or better, but still at a small fraction of its computational cost.

With a successful machine-learned potential, we can compute the energy and forces on an arbitrary configuration of ions, although the price may be to lose any explicit representation of the distinct physical effects that 20th-century models tried to capture (Behler and Csányi, 2021; Unke et al., 2021). The most successful current schemes (Behler and Parrinello, 2007; Bartók et al., 2010;

Drautz, 2019) require the total energy to be expressed as a sum over atoms of atom-centered short-ranged functions of the atomic coordinates within some cut-off radius. The functions should ideally form a complete basis to describe uniquely *all* possible arrangement of ions within the cut-off while respecting the symmetries of rotational invariance and permutations of identical elements (Bartók et al., 2013; Dusson et al., 2022). This is typically done using local per-atom *descriptors* (local, per-atom) which are combined in global structural *representations* to provide invariant or equivariant features over the relevant symmetry groups.

An alternative to manually constructing representations, which satisfy the required symmetries, is to learn the representation together with the mapping from atomic positions to energies and forces. This approach has seen considerable recent success through equivariant (Batzner et al., 2022) and message-passing (Bartók et al., 2022a, b) neural networks, which have been shown to provide improved accuracy and transferability over the descriptor-based approaches discussed above.

Although dramatic progress has been made for elemental metals and insulators, and to an increasing extent multicomponent materials (Byggmästar et al., 2021; Darby et al., 2022), the evident long-ranged interactions that we have discussed for ionic materials pose a challenge to this approach. While charge transfer among ions may be described by short-ranged functions, their Coulomb interactions are long-ranged, and alter the electron distribution and energy associated with every ion in a way that cannot be captured by a mapping of the configuration of its near neighbors. This is a nuanced matter, however, since the restricted functional forms used in empirical potentials can drastically limit their predictive accuracy even when full electrostatics are taken into account: for example, a recent machine learning potential for silica (Erhard et al., 2022) nonetheless achieves higher accuracy than empirical potentials on a range of structural and thermodynamic properties despite using a radial cut-off of just 5 Å.

To make further progress, the local energy idea has to be augmented in some way to account for long-ranged and self-consistent Coulomb interactions, as we discussed for tight-binding models, and some significant progress has been made in this direction, notably in the *PhysNet* approach of Unke and Muwly (2019), which includes long-range interactions using partial charges learned from DFT at the same time as the energies, and through charge-equilibration schemes, which combine environment-dependent atomic electronegativities with accurate atomic energies (Ko et al., 2021; Staacke et al., 2022). The rapid progress and high level of research activity in the field are grounds for optimism.

Conclusion

The nature of the bonding in ionic crystals is fundamental to the way the computer simulation of them is carried out. This article has focussed on reviewing how the interatomic forces can be modeled. We have presented a unified view of a hierarchy of well-known, classical models by showing how they can all be derived from Kohn–Sham DFT, a standard quantum-mechanical description of the bonding. This physics-based approach to the functional form of a model employs perturbation theory and a sequence of judicious approximations. Although DFT itself is a very accurate and widely used model for calculating interatomic forces in a range of materials, with simplified models much larger systems can be simulated for longer times, and this enables new data and insights to be gained about processes in materials, and facilitates the calculation of thermophysical properties. The earliest and best-known model is the simple rigid-ion model, in which the ions carry fixed charges, interacting at a separations r via the long-ranged $1/r$ Coulomb potential, combined with short-ranged, repulsive pairwise interactions. Increasing levels of sophistication and accuracy require the ions to be deformable, typified by the shell model and, for consistency with known elastic constants, they should also be compressible. To go beyond this and acknowledge that there are no *purely* ionic materials requires the introduction of charge transfer between the ions, such as the ReaxFF model. All these models can be derived as simplified versions of tight-binding models which themselves are derived from DFT, but the choice usually involves a trade-off between the requirements of speed and accuracy. Finally, we have described alternative approaches to constructing models of interatomic forces that are becoming more prominent because they promise near-DFT accuracy at a fraction of the cost. Such models rely on DFT as the engine for generating a large database of energies, forces, and structures, to which very flexibly expressed potentials and forces are fitted or machine-learned. They have already proved to be a powerful tool in the realm of metallic elements, but there are still major challenges posed by the long-ranged interactions and charge-transfers in ionic materials, which require special treatment. Nevertheless, progress in the field is evident, and we are optimistic that such potentials will make an impact in the near future.

Abstract

Metal bonds differ from ionic and covalent bonds in the degree of delocalization of electrons between nuclei. In this chapter we will use the ideas of band theory to look at the way these delocalized electrons can be described mathematically. A tight binding approach helps identify electron states that stabilize the structure (bonding states) or destabilize the system if occupied (anti-bonding states). Density of states per energy unit is compared between bands formed from different atomic orbitals in 1-D examples. Band theory is then applied to understand the crystal structures taken on by the first row transition metals.

Key points

- Metal bonding is the result of a delocalization of electrons across many atoms.
- To understand metallic bonding, we must look into the band theory of electronic states in crystalline materials.
- Tight binding theory is one way to develop a band structure for a model based on a linear combination of atomic orbitals.
- The band structure gives a rationale for the energies of electronic states which depends on the crystal structure.
- We can use the band structure and density of states to rationalize the crystal structures adopted by different metals.

Introduction

Metals form an important class of technological materials that are exploited widely for their ductility and high electrical and thermal conductivities. The general physical definition of the metallic state is based on these macroscopic properties. In this article the electronic structure of metals is considered based on a simple extension of the linear combination of atomic orbitals, that is used to describe bonding in molecules, but applied to the solid state. This makes it possible to define the metallic state precisely using the crystal orbitals responsible for bonding and so consider the importance of the metallic state in the cohesive energy of solids and its influence on structure.

The types of bonding discussed in this section of the *Encyclopedia* can be broadly divided into localized effects, involving only a few atoms in the vicinity of the chemical bond, and de-localized effects involving co-operative interactions between many atom centers. Localized interactions include covalent and hydrogen bonding while ionic and van der Waals interactions may be classed as de-localized. The concept of the Metallic bond is a little more difficult to define rigorously and has been the subject of much debate. Broadly speaking, the metallic bond can be considered as the sharing of electron density by multiple atomic centers in condensed phases. What allows us to distinguish Metallic bonding from other situations is the electronic character of the bond. The classic view of the metallic bond in solids is the “sea of electrons” concept which gives the impression of de-localization of the electrons in metallic systems. The metallic bond in this picture is an extreme example of the covalent bond and it has been suggested that the metallic bond as a concept can be subsumed into this class of bonding. However, the metallic state requires a combination of de-localized crystal orbitals and knowledge of their occupation and is a collective property of the entire electron density rather than a few specific states. In this article these ideas will be expanded and the influence of the metallic state of a solid on its stability and structure will be considered.

[☆]Change History: April 2023. D.J. Willock updated all sections and figures.

Fig. 1 Schematic illustration of the build-up of a band of states from the aggregation of H atoms. N is the number of atoms in a bulk sample and will be of the order of the Avogadro Constant ($6.022 \times 10^{23} \text{ mol}^{-1}$). Insets show the molecular orbitals for the H_2 molecule and for the top and bottom of the condensed phase band of states.

The limit of very weak interaction between the atomic cores and the valence electrons is usually employed to build a model of the electronic states in metals using the nearly free electron approximation (Kittel, 2018). In this contribution the opposite approach will be used in which crystal orbitals are built up from atomic orbitals. This gives better insight into the chemical bonding nature of the metallic state.

Band structure

The idea of a chemical bond as the sharing of electron density between atoms can be rationalized by the formation of molecular orbitals from atomic orbitals. For example, a hydrogen atom has a $1s^1$ configuration and when the orbitals from two atoms overlap in molecular H_2 they can combine in two ways. Firstly, overlap between the $1s$ orbitals can be constructive, leading to a build up of charge between the two nuclei and giving an interaction between the atoms that lowers the energy compared to the atomic state. This favors H_2 formation through the formation of a bonding orbital (σ in Fig. 1). The alternative is destructive interference between the atomic orbitals in the overlap region. This leads to a lowering of the electron density in the inter-atomic region compared to two non-interacting atoms at the same positions. If this molecular orbital is occupied a de-stabilizing contribution to the energy is obtained and the total energy is higher than that of the isolated atom states. This molecular orbital is, therefore, anti-bonding in nature (σ^* in Fig. 1). In molecular H_2 each atom supplies a single electron and so the bonding orbital is fully occupied (2 electrons) and the anti-bonding orbital is not occupied, so overall the bond is favored.

Fig. 1 also shows a schematic representation of the interactions of atomic orbitals in larger aggregations of H atoms. The difference in energy of the molecular orbitals and atomic orbitals are influenced by two main factors. Firstly, the degree of overlap between atomic orbitals; the more overlap the bigger the perturbation from the atomic state. Secondly, the energy of the two atomic orbitals; when these are well matched the difference between the energies of the molecular and atomic states is greater than when they are very different in energy. In the case of the H_2 molecule the orbital energies for the atomic states are identical and so this is optimal. If a third H atom is included the additional s -orbital will interact only weakly with the molecular orbitals of the H_2 molecule since the bonding and anti-bonding states are well separated in energy from the atomic state of the new atom. As more atoms are introduced to produce the 1-D solid the same number of molecular orbitals are formed as $1s$ orbitals that are supplied, but the energy range for the set of orbitals increases only slowly with the number of atoms. Making the leap to the 1-D solid with some large number of atoms (N in Fig. 1) there will be N crystal orbitals spread over an energy range not too dissimilar to the gap between the H_2 bonding and anti-bonding orbitals. There are now too many crystal orbitals to illustrate them all. Fig. 1 does show the extreme cases of the lowest energy crystal orbital with all bonding between neighboring atoms and the highest energy crystal orbital with all anti-bonding interactions between neighbors. In general, states at the bottom of the band will be stabilizing for crystal formation from gaseous atoms since they are lower in energy than the atomic $1s$ states. The states above the band center in this situation are destabilizing since they have higher energies than the atomic $1s$ states. In this simple example a filled band has zero contribution to the lattice energy overall.

Tight Binding approximation

The approach of building up condensed phase crystal orbitals based on molecular orbital theory can be given some mathematical structure by defining the linear combinations of atomic orbitals that are present in the 1-D chain, (Hoffmann, 2002) (Fig. 2).

The appropriate linear combination of atomic orbitals will be:

$$\psi_p = \sum_n c_{pn} \chi_n$$

Fig. 2 An idealized one-dimensional array of atoms, each atom contributes a single s -orbital to the system, the lattice parameter, a , is shown as the separation between neighbors so the unit cell contains a single atom.

where c_{pn} is the coefficient for the p^{th} crystal orbital constructed from the local atomic functions, χ_n , at each site, n , in the lattice. From the discussion above, if there are N atomic orbitals in the crystal there must be N values of p . The possible values of p can be found by considering the effect of crystal translational symmetry on the electron density.

The density of electrons, $\rho(X)$, at any point, X , in the crystal is related to the crystal wavefunctions via:

$$\rho(X) = \sum_p^{N_e/2} \psi_p^*(X) \psi_p(X)$$

where N_e is the number of electrons to be accommodated in the crystal orbitals and “*” signifies the complex conjugate. The density of electrons can be observed experimentally using X-ray diffraction, whereas the crystal orbitals are not experimental observables. Translational symmetry implies that the density must be the same at all equivalent points in the crystal. In the one dimensional lattice with repeat unit, a , this means that the densities at a point x in one unit cell and at any point $X = x + na$ (where n is any integer) must be the same. The wavefunctions need not have the same property but this restriction on the density can be met if, for any crystal orbital:

$$\psi_p^*(x + na) \psi_p(x + na) = \psi_p^*(x) \psi_p(x)$$

This leads to the expression of the crystal wavefunctions as Bloch functions:

$$\psi_k(X) = u(X) \exp(i kX)$$

Here $i = \sqrt{-1}$. The term $u(X)$ describes a periodic array of the functions local to the unit cells of the crystal:

$$u(X) = \sum_n \chi_n(X - na)$$

Fig. 3A shows $u(X)$ for the example of a line of s-orbitals, this time drawn as the radial function for the orbital at each lattice site. Provided we think of the line of atoms as effectively infinite this sum over local site functions is periodic in the lattice vector because

Fig. 3 Plots of the real part of a periodic wavefunction based on Bloch functions. The radial part of each local atomic function is modulated by the periodic function with the k -vector indicated. The atomic positions are numbered on the axes.

a shift by a whole number of lattice vectors would not change the function. This is equivalent to ignoring surface effects in real crystals when dealing with bulk properties.

The complex exponential term in the Bloch function is also periodic via the standard mathematical relation:

$$\exp(i k X) = \cos(kX) + i \sin(kX)$$

Then

$$\psi_k^*(x + na)\psi_k(x + na) = u(X)^2 \exp(-ikX) \exp(ikX) = u(X)^2 = \psi_k^*(x)\psi_k(x)$$

As $u(X)$ has the periodicity of the lattice so does the density derived from crystal orbitals based on Bloch functions, as required. Fig. 3B shows an illustrative example for the case of $k = 2\pi/(5a)$ with the real and imaginary parts of the wavefunction plotted separately and then the product $\psi_k^*\psi_k$ to show graphically that the Bloch functions give contributions to the density with the same periodicity as the lattice. In Fig. 3B the real and imaginary parts of the $\exp(ikX)$ term for the state are shown as dashed lines. This demonstrates how the complex exponential term controls the periodicity of the phase pattern of the crystal orbital along the atomic row on a length scale greater than the cell vector. In this example, the wavefunction is periodic on a scale of $5a$.

Fig. 4 gives some further examples of the real part of periodic wavefunctions with different k -vector values. For this line of s-orbitals, $k = 0$ (Fig. 4A) corresponds to the all-bonding orbital that we identified earlier as the lowest energy crystal orbital. The $k = \pi/a$ Bloch function (Fig. 4D) corresponds to the all anti-bonding condition between neighbors that gives the highest energy crystal orbital for a line of s-orbitals. Fig. 4B and C also show the $k = \pi/(3a)$ and $k = 2\pi/(3a)$ solutions which repeat over $6a$ and $3a$ respectively. These orbitals have intermediate energies as they contain a mix of bonding and anti-bonding interactions between neighbors. Fig. 4 illustrates that the degree of anti-bonding in this example increases with the magnitude of the k -vector.

The wave-vector, k , is commonly used as the label for the crystal orbitals as has been done above, it is related to the integer p via:

$$k = \frac{2\pi p}{Na}, \quad p = -\frac{N}{2}, \dots, -1, 0, 1, \dots, \frac{N}{2}, \quad k = -\frac{\pi}{a}, \dots, 0, \dots, \frac{\pi}{a}$$

The integer p has $N + 1$ values, however the $p = -N/2$ and $p = N/2$ cases are equivalent, both would give solutions periodic on a length scale of $2a$ (see Fig. 4D). This means that the N atomic orbitals that are combined will form N crystal orbitals ($2N$ electronic states).

Fig. 4 Example plots for the real part of Bloch functions for the cases (A) $k = 0$, (B) $k = \pi/(3a)$, (C) $k = 2\pi/(3a)$ and (D) $k = \pi/a$. In each case the atomic positions are numbered on the x -axis and the real (cosine) part of the $\exp(ikX)$ term is shown as a dashed line.

The k -vectors have units of reciprocal length and allowed values ranging from $-\pi/a$ to π/a . Now another lattice or line of points can be constructed for the values of k that give valid Bloch functions for the lattice. This line is related to the real space row of atomic sites but the lattice points give the periodicities of waves with reciprocal length units, i.e. they are points in reciprocal space. The allowed values of k define the range in reciprocal space occupied by the unique Bloch states which is known as the Brillouin zone.

Using the crystal orbitals in the Schrödinger equation gives the orbital energy as a function of the wavevector k :

$$E_k = \frac{\int_{-\infty}^{\infty} \psi_k^* H \psi_k dx}{\int_{-\infty}^{\infty} \psi_k^* \psi_k dx}$$

Here, H , is the Hamiltonian describing the interaction of the electron in the crystal orbital with the line of atoms. The crystal orbitals in terms of Bloch states allow the numerator and denominator of this expression to be written as:

$$\int_{-\infty}^{\infty} \psi_k^* H \psi_k dx = \sum_n \sum_m^N \exp(ik(na - ma)) \int_{-\infty}^{\infty} \chi_n^*(X - na) H \chi_m(X - ma) dX$$

and

$$\int_{-\infty}^{\infty} \psi_k^* \psi_k dx = \sum_n \sum_m^N \exp(ik(na - ma)) \int_{-\infty}^{\infty} \chi_n^*(X - na) \chi_m(X - ma) dX$$

In which m and n are integers identifying sites along the row of atoms and now the integrals required are over the local atomic functions. To obtain a qualitative insight into the band structure the simplifying tight binding approximations can be used which give the integrals required for the numerator the values:

$$\begin{aligned} \int_{-\infty}^{\infty} \chi_n^*(X - na) H \chi_m(X - ma) dX &= \alpha & m = n \\ \int_{-\infty}^{\infty} \chi_n^*(X - na) H \chi_m(X - ma) dX &= \beta & m = n \pm 1 \\ \int_{-\infty}^{\infty} \chi_n^*(X - na) H \chi_m(X - ma) dX &= 0 & m < n - 1 \text{ or } m > n + 1 \end{aligned}$$

That is to say, the on-site term is given the parameter, α , the term for nearest neighbors the parameter, β , and all other terms are simply ignored. This concentration on local interactions is the reason the approximation itself is called “tight binding”. Although the interaction contributions are considered in this way the crystal orbitals are still de-localized along the entire chain of atoms. For the denominator the tight binding approximation is even more severe:

$$\begin{aligned} \int_{-\infty}^{\infty} \chi_n^*(X - na) \chi_m(X - ma) dX &= 1 & m = n \\ \int_{-\infty}^{\infty} \chi_n^*(X - na) \chi_m(X - ma) dX &= 0 & m \neq n \end{aligned}$$

So the overlap between an atomic orbital with itself is taken to be 1 and the overlap between neighboring sites and beyond is taken to be insignificant. Using these integral values in the energy expression gives the formula:

$$E_k = \alpha + 2\beta \cos(ka)$$

The factor of 2 occurs as each site has one neighbor to the left and one to the right in the chain. The energy of a particular crystal orbital depends on the local energy terms and the wave-vector of the orbital. For a given system the local interaction integrals are simply fixed parameters. In general the relationship between the energy, E_k and the wave-vector of the state, k , is termed the dispersion relation.

This model can now be applied to the band of states for the 1-D chain of hydrogen atoms for which the local functions are s -orbitals on each H atom. As we saw in Fig. 4, when $k = 0$ the exponential factor in the crystal orbital Bloch function is 1 and so all site orbitals are in phase giving a low energy contribution. In contrast, when $k = \pm \pi/a$ the complex exponential gives a wave that changes sign between neighboring unit cells of the crystal and so all neighboring orbitals have an anti-bonding interaction, a high energy contribution. The dispersion equation provides a way to calculate a numerical estimate of the energy of the crystal orbital for any k -value and so quantify the difference between bonding and anti-bonding. Fig. 5 shows the resulting dispersion relation for a line of s -orbitals from the tight binding approximation. The low energy states are around $k = 0$ while for k near its limiting values of $\pm \pi/a$ the energy of the states are higher than for the isolated atomic orbitals, implying that β is negative. The overall band width is 4β , so the strength of interaction between neighboring sites controls the band width. The energy of the band center ($k = \pi/(2a)$) from the dispersion relation is the α parameter value, as the cosine term is zero at this point. So the on-site orbital energy term controls the position of the band on the energy axis.

Fig. 5 The dispersion relation for a line of s-orbitals from the tight binding approximation. In this example we have taken $\alpha = 1$ and $\beta = -3$ with arbitrary energy units. The choice of negative β corresponds to bonding overlap between neighboring unit cells at $k = 0$.

The allowed values of k are defined with the quantum number p , are evenly spaced in reciprocal space at intervals of $2\pi/(Na)$. However, the relationship between the energy and the k -vector is not linear. In particular, near the Brillouin zone boundary the dispersion curve flattens, so that many k -vectors in this region have almost the same energy. In one dimension a similar effect is seen at the zone center. The density of states (DOS), $N(E)$, is defined as the number of energy levels within a small energy increment as a function of the state energy. In one dimension the regions in which the dispersion curve flattens out lead to a higher DOS than in regions in which the dispersion curve is steep.

Band filling and metallic behavior

The metallic state can now be defined based on the electron occupancy of the crystal orbitals. For the line of s-orbitals from hydrogen atoms there are N -crystal orbitals and the Pauli exclusion principle dictates that each orbital can contain a maximum of 2 electrons, one spin up and one spin down. The crystal orbitals, therefore, give rise to $2N$ electron states, each hydrogen atom delivers one electron and so the states are half filled. This assumes that states are simply filled from the lowest energy upwards until all electrons have been placed in crystal orbitals. However, since the energy separation of states within a band is extremely small, this strict ordering is only possible at zero Kelvin. At any finite temperature an electron at the top of the occupied levels can be promoted to the un-occupied states by thermal excitation. The probability of occupancy of a state, $f(E_k)$, is controlled by Fermi-Dirac statistics:

$$f(E_k) = \frac{1}{1 + \exp\left(\frac{E_k - E_F}{k_B T}\right)}$$

Here E_F is the Fermi energy which, in metals, corresponds to the energy of the highest occupied state at zero Kelvin, k_B is the Boltzmann constant and T the temperature. More generally E_F is defined from this formula as the energy at which the probability of occupancy is exactly one half.

Fig. 6 shows plots of the Fermi-Dirac probability function at different temperatures. At 0 K it can be seen that the low energy states are filled up to E_F but above E_F all states are empty. At higher temperatures, however, electrons from below the Fermi energy can be promoted to the higher states, leading to the tail feature. These promotions can only occur if there are states available to receive the electrons that are excited. In the one dimensional H example the band of $2N$ states is half filled and so there are states available for the thermally excited electrons to move into. This situation gives rise to the electrical and thermal conduction in metals, filled and empty states are so close together that the promotion of electrons at energies close to E_F can occur easily. These electrons at the interface between the occupied and un-occupied states are active in transport giving rise to the metallic behavior of the solid. Accordingly, condensed hydrogen is expected to be a metal.

The construction of the crystal orbitals also show that the occupied states are those which are largely bonding and so solid H is favored over separated gas phase H atoms. In the laboratory, the liquid state of H has been achieved at low temperature and very high pressure using shock wave pressure methods and is found to have metallic conductivity. However, under most circumstances, $N/2$ diatomic molecules is an even more stable situation and so the diatomic gas is the normal state.

There are a few less exotic examples of solids with 1-D aspects to their electronic structure. For example, the solid formed by salts of the $[\text{Pt}(\text{CN})_4]^{2-}$ anion contain square planar complexes stacked in the crystallographic c -direction. In the simple $\text{K}_2[\text{Pt}(\text{CN})_4]$ salt (Fig. 7A) neighboring Pt centers are 3.48 Å apart. Within each complex the Pt atom is in the 2+ oxidation state and so has a d^8 electron configuration. Fig. 8 shows each orbital type and their arrangement along the line of complexes for the

Fig. 6 Plots of the Fermi-Dirac statistics function for temperatures of 0 K, 300 K and 1000 K. This example has the value of E_F set to 1 eV.

Fig. 7 Chain structures formed by $[\text{Pt}(\text{CN})_4]^{2-}$ in the solid state. (A) From $\text{K}_2[\text{Pt}(\text{CN})_4]$, (B) from $\text{K}_2[\text{Pt}(\text{CN})_4] \cdot \text{Br}_{0.3}$. For clarity cations, dopants and water of crystallization have been omitted. Atom colors: C: gray, N: blue and Pt: purple.

Fig. 8 The arrangement of orbitals for the $k = 0$ wave-vector case for a chain of atoms along the Z -axis. (A) d_{z^2} , (B) $d_{x^2-y^2}$ or d_{y^2} , (C) d_{xy} , $d_{x^2-y^2}$ have the same bonding symmetry but with orbitals rotated 45° in the xy plane, (D) p_z .

Fig. 9 The dispersion curves and density of states (DOS) for the bands formed along the stacking direction in $K_2[Pt(CN)_4]$ by the Pt centered orbitals.

$k = 0$ wave-vector. By convention the Z-direction for defining the orbital orientation is aligned with the stacking direction of the complexes. Fig. 9 shows the dispersion plots in the positive k -vector region for each of the bands formed. The interaction with the CN^- ligands puts the energy of the molecular anti-bonding orbital involving the $d_{x^2-y^2}$ atomic orbital above the other d-orbitals. In terms of tight binding theory this means that the α parameter is larger for $d_{x^2-y^2}$ than the other d-orbitals and so this is un-occupied. The dispersion curves of the bands formed between the metal centers depend on the symmetry of the orbitals with respect to the chain direction. At $k = 0$, the d_{z^2} orbital has a bonding arrangement, similar to the s-orbitals used in the hydrogen example, and so the dispersion curve for this band is similar to Fig. 5. The d_{xz} and d_{yz} orbitals form a degenerate pair of bands in which the $k = 0$ orbital is anti-bonding, which means that the energy of the crystal orbitals decrease as k approaches π/a . The tight binding parameter, β , in this case is positive. These orbitals also have π -symmetry (Fig. 8B), rather than σ , which leads to a weaker overlap between neighbors and so a smaller magnitude for the tight binding β -parameter. Since the band width is 4β this results in a narrower range of energies in the band than for d_{z^2} . The d_{xy} and $d_{x^2-y^2}$ orbitals both have δ -symmetry bonding interactions at $k = 0$ (Fig. 8C) so the bands are narrower still. The 6p orbitals of Pt are empty within the complex, however the molecular orbital involving the Pt p_z orbital is only just higher in energy than $d_{x^2-y^2}$. The symmetry of the p_z orbital gives σ anti-bonding at $k = 0$ (Fig. 8D) while at $k = \pm\pi/a$ each alternate p_z orbital is inverted, giving a bonding arrangement. For orbitals with this symmetry, states at the Brillouin zone boundary are lower in energy than at the center and so the dispersion relation appears inverted compared to orbitals with bonding at $k = 0$.

In the dispersion curves for these bands of the Pt complex stacks (Fig. 9) the four occupied complex orbitals involving d_{z^2} , d_{xy} , d_{xz} and d_{yz} have similar energies and so have been assigned the same α -parameter, this means they cross at $k = \pi/(2a)$. All four orbitals form a continuous band of states. However, the strength of interaction between neighbors is not the same in them all and so they have different band widths as discussed above. The $d_{x^2-y^2}$ and p_z orbital form another overlapping set of bands. The p_z orbital states on the complexes are above the $d_{x^2-y^2}$ however the interaction between neighbors is stronger for the p-orbitals and so the p_z -band is wider, leading to the lowest un-occupied states being p_z in nature.

Just as the line of H orbitals gave the same number of crystal orbitals as the number of atomic orbitals in the line each of the d-orbitals in the Pt stack will have the same number of crystal orbitals in the corresponding bands. This means that when we look at the DOS in Fig. 9 the area under the contribution to the DOS from each band is the same and so bands with a narrow band width will have a relatively high density of states. We have seen that the band width is controlled by the β parameter in the tight binding theory and so the weaker the overlap between orbitals in neighboring unit cells the narrower the band and the higher the density of states per unit energy. Also, in Fig. 9 we can see that the degenerate d_{xz} and d_{yz} bands generate twice the DOS of contributions from single orbitals.

For $K_2[Pt(CN)_4]$ there is a band gap between the occupied and unoccupied states so the material is a semi-conductor in the chain direction. However, metallic behavior can be induced by the addition of halide dopant ions to give chemical formulae such as $K_2[Pt(CN)_4] Br_{0.3}$. This is a level of "dopant" much greater than used in classical semi-conductors such as silicon and so the concentration of extrinsic carriers is correspondingly higher. The halide anions withdraw electrons from the Pt chains giving empty

states in the top of the occupied band and placing the Fermi level at the interface between filled states and empty states in the band. Measurements confirm that the electrical conductivity is 10^4 – 10^5 times greater along the stack direction than perpendicular to it in the doped material. The crystal structure is also strongly affected by this change to a metallic form. The Pt-Pt distance in the doped material is 2.89 Å, not much greater than in Pt metal (2.78 Å). This reduction in Pt-Pt distance can be understood in terms of the bonding character for the chain states. In the $K_2[Pt(CN)_4]$ material there is a completely filled band of states and so both bonding and anti-bonding crystal orbitals are occupied. When the dopant is added charge is withdrawn from the high lying anti-bonding states and the free Fermi surface corresponds to an overall bonding character from the crystal orbitals. The increased bonding along the chain direction leads to the observed shortening of the Pt-Pt distance. To accommodate this there is also a rotation of alternate complexes to avoid steric clashes between CN ligands, as can be seen in Fig. 7B.

Band structure in three dimensions

It is more common for crystals to contain bonding between metal atoms in X, Y and Z directions. This is the case in elemental metal solids and metal alloys. In three dimensions (3-D) the unit cells of solids are described by a packing volume with sides defined by vectors, $\underline{a}$, $\underline{b}$ and $\underline{c}$. A position anywhere in the crystal, $\underline{R}$, can then be written based on the cell vector directions:

$$\underline{R} = \underline{r} + \underline{T}$$

where the vector, $\underline{r}$, is a position in an arbitrary reference unit cell:

$$\underline{r} = f_a \underline{a} + f_b \underline{b} + f_c \underline{c}$$

The f coefficients being the fraction of the cell vector in the direction indicated by the subscript defining the position of a point in the reference unit cell.

The vector, $\underline{T}$, is a translation vector between unit cells:

$$\underline{T} = n_a \underline{a} + n_b \underline{b} + n_c \underline{c}$$

Where n is an integer for the number of unit cells in the direction indicated by the subscript from the arbitrary reference cell to the cell containing the position $\underline{R}$.

Correspondingly, the reciprocal wave-vectors have three components in reciprocal space. The reciprocal space unit cell has dimensions related to the real space unit cell by the relations:

$$\underline{a}^* = \frac{2\pi}{V_c} \underline{b} \times \underline{c} \quad \underline{b}^* = \frac{2\pi}{V_c} \underline{c} \times \underline{a} \quad \underline{c}^* = \frac{2\pi}{V_c} \underline{a} \times \underline{b}$$

Where V_c is the volume of the unit cell, “ $\times$ ” means a vector cross-product and superscript “*” refers to the reciprocal lattice. As $V_c = \underline{a} \cdot (\underline{b} \times \underline{c})$, these reciprocal space cell vectors have units of reciprocal length and an alternative way to write the reciprocal space vectors is:

$$\underline{a}^* = \left(\frac{2\pi}{a}, 0, 0 \right) \quad \underline{b}^* = \left(0, \frac{2\pi}{b}, 0 \right) \quad \underline{c}^* = \left(0, 0, \frac{2\pi}{c} \right)$$

Where the cell vector letter without the underline refers to the scalar length of the vector. The bracket notation has the components of the vectors in the order of the cross product directions. For orthogonal cells, $\underline{a}^*$ is aligned with $\underline{a}$, $\underline{b}^*$ with $\underline{b}$ and $\underline{c}^*$ with $\underline{c}$, but not all cells are orthogonal so the use of the cross products to define the directions keeps the discussion general for any crystal structure.

The k -vector in 3-D can now be expressed as a combination of reciprocal vectors:

$$\underline{k} = f_a^* \underline{a}^* + f_b^* \underline{b}^* + f_c^* \underline{c}^*$$

where the factors, f , are fractional values from $-\frac{1}{2}$ to $+\frac{1}{2}$ controlling the repeat of the wave vector in the direction indicated by the subscript.

This leads to straightforward generalization of the Bloch function to 3-D, (Ashcroft and Mermin, 1976):

$$\psi_{\underline{k}}(\underline{R}) = u(\underline{R}) \exp(i \underline{k} \cdot \underline{R})$$

For example, if we take the k -vector with $(f_a^*, f_b^*, f_c^*) = (\frac{1}{2}, 0, 0)$, i.e., $\underline{k} = \frac{\underline{a}^*}{2} = \left(\frac{\pi}{a}, 0, 0 \right)$,

$$\psi_{\underline{a}^*/2}(\underline{R}) = u(\underline{R}) \exp\left(i \frac{\underline{a}^*}{2} \cdot \underline{R}\right)$$

the argument of the complex exponential becomes,

$$\frac{\underline{a}^*}{2} \cdot \underline{R} = \left(\frac{\pi}{a}, 0, 0 \right) \cdot ((n_a + f_a)\underline{a} + (n_b + f_b)\underline{b} + (n_c + f_c)\underline{c}) = \pi(n_a + f_a)$$

Fig. 10 Illustration of Bloch functions using an fcc crystal structure example. (A) $\underline{k} = (\frac{\pi}{a}, 0, 0)$ the dashed curve shows the relation of the real part of the complex exponential to the unit cell and planes in the crystal are used to show the periodicity in the 3-D structure. (B) $\underline{k} = (\frac{\pi}{a}, 0, \frac{\pi}{c})$. In both cases the cell vectors are slightly displaced from the unit cell boundaries for clarity and the bold arrow shows the crystal direction in which the function is periodic labeled with the $\underline{k}$ -vector.

which means the crystal orbital is periodic on scale of $2a$ in the $\underline{a}^*$ direction because the wavefunction value at any position with a fractional co-ordinate f_a would be the same as that at any equivalent position related by an even number of cell translations in the $\underline{a}$ direction. This is illustrated in Fig. 10A using a set of planes drawn over three unit cells of a face centered cubic (fcc) crystal structure to show the repeating pattern for the $\underline{k} = (\frac{\pi}{a}, 0, 0)$ Bloch function.

Fig. 10B, illustrates the $\underline{k} = (\frac{\pi}{a}, 0, \frac{\pi}{c})$ orbital which is a phase pattern orientated to give a wave pointing diagonally at 45° in the ac plane for this cubic crystal.

These two examples show that the periodicity of the lattice will be different according to the direction considered. This in turn means that, rather than the Brillouin zone defining a single range for k , its extent will depend on the direction taken so that the Brillouin zone becomes a volume of the reciprocal space. The first Brillouin zone is the shape formed by the Wigner-Seitz cell in this lattice. This is the primitive cell constructed by taking the intersections of planes placed at the half way point between each reciprocal lattice point. At all points on the surface of this volume the k -vector will have a value of $\pm\pi/d$ (d now being the repeat distance in the corresponding direction in the real space lattice).

The shape of the Brillouin zone is linked to the structure adopted by the metal. Examples of the Brillouin zone for two common structures found in elemental metals, body centered cubic (bcc) and face centered cubic (fcc) are shown in Fig. 11.

The geometry of the crystal will also affect the band structure. Based on tight binding theory we should include a β term for each nearest neighbor. In 1-D this gives a factor of 2, for bcc the factor will be 8 and for fcc there are 12 nearest neighbors for each atom. So, the dispersion relation itself is dependent on the structure adopted by a particular metal.

The vector nature of $\underline{k}$ in 3-D also influences the number of states as a function of energy, which was introduced in 1-D as the density of states (DOS). The number of states at a particular energy will depend on the number of possible k -vectors that have equivalent state energies. For large values of k there are many k -vectors with the same magnitude but with different directions in reciprocal space, leading to a high degree of degeneracy. This, coupled with the flattening of the dispersion relation, leads to a high DOS at large k . In contrast with the 1-D situation, however, at the zone center there are only a few wave-vectors of the same length and so although the dispersion relation may flatten out there is no longer a significant increase in the DOS. Indeed, at the zone center, $\underline{k} = (0,0,0)$, all three components are zero and so there is only one state.

In this picture, when E_F is far from the Brillouin zone edge, the k -vectors of the states at the Fermi level define the surface of a sphere centered on the origin. An example is shown in Fig. 12A for the case of Na metal. Here one electron per atom is present but the band is formed from the atomic 3s and 3p orbitals with only the lowest lying crystal orbitals occupied. This leads to a near perfect sphere representing the boundary between occupied and unoccupied crystal orbitals. Fig. 12B the example of the Brillouin zone for the fcc metal Cu is shown with the Fermi surface included. Copper is a transition metal with a valence shell configuration of $4s^1 3d^{10}$ so the electron density is higher than for sodium. The directions in reciprocal space where the distance from the origin to the Brillouin zone edge is shortest is along the directions equivalent to $\underline{k} = (1,1,1)$, i.e. vectors in which all three components have the

Fig. 11 The first Brillouin zone for the real space lattices of, (A) bcc structures and (B) fcc structures. Note that the reciprocal space lattice of the bcc lattice is actually fcc and *visa versa*.

Fig. 12 The Fermi surface defining the extent of occupied states in the Brillouin zone for the examples of, (A) Na, which has the bcc structure and (B) Cu, which has the fcc structure.

same magnitude. For Cu crystal orbitals with k -vectors in these directions are fully occupied and as the dispersion relation flattens off near the zone edge round tube like features appear. In other directions the Fermi surface still falls short of the Brillouin zone boundary, so Cu still has a large area of free Fermi surface. This leads to the excellent electrical and thermal conductivity of copper metal.

Dependence of metallic structure on the density of states

The shape and volume of the Brillouin zone controls the electron density at which the Fermi surface touches the Brillouin zone boundary. Near the boundary the dispersion curve flattens off leading to an increased DOS. Differences in the reciprocal lattices between structures will affect the point at which this occurs and so different crystal lattices will have different total electronic energies at a given density.

For example, Fig. 11 shows the shape of the Brillouin zones for the fcc and bcc lattices. The points in the diagrams represent the points on the reciprocal space lattice at the spacing set by the reciprocal space vectors. In fact, the reciprocal space primitive vectors for the fcc lattice are the same as the real space bcc primitive vectors and *visa versa*.

Fig. 13 shows a sketch of the DOS for the fcc and bcc crystal structures. At low electron density all occupied states are well within the Brillouin zone boundary and so the DOS simply increases with the state energy as the number of degenerate k -vectors also increases. As the wave-vectors approach the Brillouin zone boundary the dispersion curve levels out and the degeneracy of states increases giving a greater DOS. However, if the energy is increased further the number of available states decreases again since only the sections of volume furthest from the center of the Wigner-Seitz cell are still available. We have seen this starting to happen for the case of Cu in Fig. 12B. At the Fermi level in Cu there are no further states available in directions like $\hat{k} = (1, 1, 1)$, but there are still empty states in the band in other directions. If we were to add more electrons, even though they would occupy higher k -states the density of states would decrease as the number of directions in reciprocal space still inside the Brillouin zone would reduce. In general, as shown in Fig. 13, this leads to a peak in the DOS in the vicinity of the Brillouin zone boundary. Because of the geometry of the reciprocal space lattices the peak occurs at lower energy for the fcc real space lattice than for the bcc case. For a metal with electron density at the fcc peak the fcc structure will be preferred because the Fermi energy will be lower than in the bcc lattice. However, if the density of electrons is near the bcc peak the fcc DOS has begun to fall dramatically and so a lower energy electron configuration is possible in the bcc structure.

The DOS of real metals is more complex than this illustration using a single band in fcc and bcc structures. However, the example does serve to show that the DOS will influence the relative total electronic energy of alternative metal lattices. Or, conversely, the electron density of a metal can have a dramatic influence on the optimal crystal structure.

This idea has been tested using higher level calculations on the first row transition metals to obtain the band structures and densities of states for the valence shells in bcc, fcc and hexagonal close packed (hcp) structural alternatives, as shown in Fig. 14, (Pettifor, 1970). The shape of the DOS for each structure is largely controlled by the interaction of the metal d-orbitals in the different crystallographic directions since the overlap of the spherical s-orbitals is less influenced by the lattice geometry. At low energies the calculated DOS are all very similar. However, at 0.35 eV, corresponding to 3 electrons per atom, the bcc plot shows a distinct dip and so at this point an increase in electron density with this structure must occupy higher energy states than are required in the close packed lattices.

In Fig. 14D, integration of the occupied state energies is used to compare the relative internal energies calculated for the different structures for each valence electron count. In this plot fcc is used as the reference. For example, if the bcc-fcc curve is positive a structure with that number of valence electrons will have a lower internal energy as an fcc lattice than it would as a bcc lattice and so the fcc structure is preferred. The hcp-fcc curve shows a much smaller range as both structures are close packed and so differences in binding energy are due to more long range effects.

As noted above the dip in the bcc DOS at 0.35 eV corresponds to around 3 electrons per atom. In Fig. 14D up to this point the bcc-fcc curve is positive and more positive than the hcp-fcc curve. So that in this regime the close packed lattices are indeed lower in energy than bcc and under standard conditions the early transition metals, Sc ($3d^14s^2$) and Ti ($3d^24s^2$) have the hcp structure. Just

Fig. 13 Schematic diagram of the DOS for the fcc and bcc crystal systems. The peaks correspond to the point when the k -vector just touches the Brillouin zone boundary.

Fig. 14 The DOS for (A) bcc, (B) fcc and (C) hcp structures. The dotted line on each diagram is the integrated DOS and shows the level of the Fermi energy in the metal with the number of electrons per atom indicated on diagram (C). (D) The total electronic energy of the bcc and hcp structures relative to that of the fcc as a function of electron density taken from (Pettifor, 1970).

above 0.4 eV there is a peak in the bcc DOS and so the total energy at the corresponding electron densities favors the bcc structure (bcc-fcc negative, Fig. 14D). Vanadium and chromium with 5 and 6 valence electrons, respectively, both adopt this lattice. Manganese has a complex structure which has not been included in this study while Fe ($3d^6 4s^2$) has the bcc structure at room temperature against the predicted fcc lattice from Fig. 14D. However, magnetic effects seem to dominate this choice of structure for Fe since above the Curie temperature the fcc structure is observed. For higher electron densities the close packed structures are found again, with the choice of fcc or hcp finely balanced. Even so, the total electronic energies indicate that at 7 and 8 valence electrons hcp is more stable than fcc while the situation is reversed for 9 and 10 outer electrons. This trend is observed experimentally, with the structures of Co and Ni being hcp and Cu and Zn taking up the fcc structure.

Conclusion

We have seen how the concept of metals being formed from the interaction of ionic cores with a sea of electrons can be made more concrete through the development of band theory. Band theory leads to the classification of electronic states that are delocalized in the crystal using the k -vector that describes the periodicity of the state wavefunction on length scales longer than the unit cell. In tight bonding theory a band of states is then formed from each orbital of the unit cell. The metallic state is then easily defined as a material in which at least one of the electronic bands is only partially filled. In these materials electrons near to the top of the filled states, i.e. those at the Fermi energy, can easily move into the empty states just above. This gives rise to the high electronic and thermal conduction properties we associate with metals. The degree of bonding/antibonding for solids can also be understood by considering the wavefunction energy relative to that of the free atoms. In a tight binding approach this is the energy for the orbital forming the band represented by the site parameter, α , and so states with lower energy than this will be bonding and those with

higher energy anti-bonding. The effect of the delocalization of the electrons is captured in the tight binding, β parameter which controls the band width. This parameter depends on the atomic arrangement in the crystal and so gives us a way to compare the stability of alternative crystal structures.

However, although the tight binding approach as described here gives conceptual insight, any two parameter model will be restricted in accuracy. Over the last 40 years increasingly sophisticated solutions to electronic structure problem have been developed, most notably through density functional theory (DFT) as reviewed by Jones (2015). Implementation of DFT for solids using computer simulations has allowed very accurate models of the electronic structure to be created bringing in not only the interaction of the valence electrons with the lattice site ions but also important electron-electron exchange and correlation energies. The crystal orbitals are still represented by Bloch functions, (Payne et al., 1992), but now the energies of the states compare accurately with experimental measurements of material properties. Indeed, by combining these methods with thermodynamic calculations of the effects of entropy on the stability of metals it is possible to predict the experimental melting and boiling points of metals, (Löffelsender et al., 2022).

Density functional theory is now a widely used practical tool helping us understand and design new approaches to thermal insulation, (Nielsen et al., 2013), energy storage, (Jain et al., 2016), catalysis, (Qi et al., 2022), and many other technologically important materials.

Abstract

Understanding the crystal properties that emerge during growth is crucial to further improve crystal quality and open the doors to novel, unprecedented applications. There is no single theory or approach that can describe the full complexity of crystal growth.

However, there are many different tools that are particularly powerful when trying to understand the underlying physical nature of related processes. This chapter attempts to provide an overview of the basic crystal growth theories, including thermodynamic concepts and kinetic considerations, emerging numerical modeling techniques such as CFD and machine learning, and crystal growth analysis involving crystal defects, morphological instabilities, and segregation.

Key points

- Introduction: This section highlights the role of theory and models in crystal growth.
- Overview and key issues: This section provides an overview of basic crystal growth theories, crystal growth modeling, and crystal growth analysis. The focus is on key issues related to thermodynamics, kinetics, continuum methods, process engineering, crystal defects, segregation and morphological instability.
- Summary and future directions: This section addresses the challenges in crystal growth theory and models, and the synergy potential of physics-based and data-driven approaches.

Introduction

Artificially grown crystals are used in a variety of technological applications such as microelectronics, photovoltaics, optics, lasers, light-emitting diodes, and telecommunication, and are therefore an essential pillar of our modern society (Scheel and Fukuda, 2003; Nishinaga, 2015). These industrially grown crystals are characterized by superior perfection compared to all crystals occurring in nature.

In the case of the economically most important semiconductor crystal, silicon, ingots are grown with weights up to 2000 kg and with defect concentrations of less than one in a billion atoms (Abrosimov et al., 2017) to meet the ever-increasing demands of the solar and electronics industry.

Our technological progress is therefore limited by the quality of such crystals, which have to be produced in complex, application-specific growth processes. Understanding the crystal properties that emerge during growth is crucial to further improving their quality and opening the doors to novel, unprecedented applications.

[☆]*Change History:* September 2022. N Dropka updated the chapter. He updated text, references, Figs. 3, 6, and 8.

There is no single theory or approach that can describe the full complexity of crystal growth, and many unanswered questions remain.

However, there are many different tools that are particularly powerful when trying to understand the underlying physical nature of related processes. This paper attempts to provide an overview of the basic crystal growth theories, emerging numerical modeling techniques, and crystal growth analysis.

Overview and key issues

Crystal growth theory

Crystallization is a phase transition from a disordered phase (vapors, solutions, and melts) into a highly-ordered solid phase, called a crystal. Crystal growth is the stage of crystallization, in which the crystal constituents (atoms, molecules) attach to the existing crystal surface, leading to the growth of the crystal. For relevant technological bulk crystal growth processes, this crystal surface is typically an existing seed crystal, where a crystal nucleus has to form before growth. The associated nucleation theory will not be discussed further here.

The crystal growth theory attempts to describe the mathematical framework of why and how crystals with certain properties grow. However, due to the wide range of materials, growth methods, and overall complexity of the process, there is no general theory describing this topic.

Important fundamental descriptions related to bulk crystal growth can be divided into thermodynamic and kinetic theories, which are discussed in sub-sections “[Thermodynamics](#)” and “[Kinetics](#)”, respectively. The main difference between these theories lies in the fact that thermodynamics describes the general tendencies why phenomena can occur, while kinetics describes the rate at which a given process occurs and the pathway by which it occurs.

Thermodynamics

Thermodynamics is an essential tool to understand a wide range of aspects of crystal growth e.g. the driving force of crystallization, stability regions of materials, stoichiometry of compounds, optimal growth conditions, shape of crystals, defect concentrations, incorporation of foreign atoms into the crystal (segregation), etc. ([Rudolph, 1998, 2003](#)).

Classical thermodynamics deals with the description of states of many-particle systems at equilibrium with respect to macroscopic physical quantities, such as pressure p , temperature T , volume V and entropy S ([Wallace, 1972](#); [Lupis, 1983](#)). These concepts can be utilized to describe crystal growth phenomena since they generally occur close to equilibrium and the related time scales are large compared to the kinetic time scale of atoms. A state of a system is at equilibrium if the free energy is minimized. The equilibrium related to the crystallization process ($T, p = \text{const.}$) is characterized by the minimization of the Gibbs free energy G of the system, which is defined as:

$$G = U + p \cdot V - T \cdot S = H - T \cdot S \quad (1)$$

where U is the internal energy and H is the enthalpy. The potential H is predominantly determined by the decrease in internal energy through the formations of atomic bonds in the crystal and is thus minimized ($H \rightarrow \min$) by the ordering process during crystallization. However, this ordering is inherent with a decrease in entropy $S \rightarrow \min$, which counteracts the minimization of G . Hence, disordering and the formation of defects ($S \rightarrow \max$) becomes more and more important with increasing temperature. In other words, there is a limit on how perfect a crystal can be, and a crystal at thermodynamic equilibrium has an associated point defect concentration, such as vacancies, self-interstitials, or impurity atoms (more on defects in sub-section “[Defects](#)”).

As a simple model, we only consider the formation energy of a defect E_d (increases G) and a defect concentration n (decreases G , through the increase of entropy). One can approximate the equilibrium defect concentration by analytical methods (shown in detail in e.g. [Gottstein, 2013](#)):

$$n = N \exp \left(- \frac{E_d}{k_B T} \right) \quad (2)$$

where N is the concentration of atoms in the crystal lattice and k_B is the Boltzmann constant. The defect concentration as a function of temperature is shown in [Fig. 1](#) for different formation energies (bold line). One can see that the defect concentrations at high temperatures (e.g. during crystal growth, close to the melting point of a material) are significant, and a diffusion-limited freeze-in of only a fraction of the equilibrium point defects has severe implications for the material quality (dashed line). The task is therefore not to grow perfect crystals, but to develop growth processes that control the defect formation to the extent necessary for the desired application.

Thermodynamics can also be employed to predict the existence and coexistence of phases under different conditions and possible phase transitions. Crystallization involves a first-order phase transition that is a discontinuous change in enthalpy, entropy, and volume. At the equilibrium point, the crystalline and the disordered phase are stable and coexist separated by a phase boundary (interface). It requires some kind of deviation from this equilibrium (temperature, pressure, concentration) to create a driving force of crystallization.

Considering a one-component system with a solid and a fluid phase close to the equilibrium point (the same is true for any two phases), one can approximate the temperature dependence of G in the solid and liquid as linear, as shown in [Fig. 2](#).

The temperature dependence of G of the fluid phase is stronger than the one of the solid phase, which is mostly caused by the entropic term $T \cdot S$ of Eq. (1). Hence, there exists a point where these functions cut, which indicates the equilibrium temperature T_e at which both phases coexist. If there are deviations from the equilibrium temperature (supercooling by ΔT), the two phases can still exist, one being stable and the other metastable. The resulting difference in Gibbs free energy ΔG between the solid and the liquid

Fig. 1 Equilibrium point defect concentration $N_{\min}$ as a function of T for defect formation energies E_d of 1 eV and 2 eV (bold line) and a schematic freeze-in of the defect concentration due to diffusion limitations (dashed line) for $N = N_A = 6.022 \cdot 10^{23} \text{ mol}^{-1}$, the Avogadro constant. Based on Rudolph P (2003) Thermodynamic fundamentals of phase transitions applied to crystal growth processes, In: Scheel HJ and Fukuda T (Eds.), *Crystal Growth Technology*, Wiley, pp. 15–42, reprinted with permission of Elsevier.

Fig. 2 Schematic temperature dependence of G (equivalent to chemical potential μ for one-component systems) for the solid S (crystal) and liquid phase L (melt) close to the equilibrium temperature T_e .

represents the driving force of crystallization. If a crystal seed is present, this leads directly to the propagation of the phase boundary into the metastable phase and subsequent crystallization. Other possible driving forces of crystallization can be changes in pressure or concentration (supersaturation). Similar considerations can be used to estimate the rate of crystal growth, as shown for example by Nishinaga (2016).

The coexistence of distinct phases ($\Delta G = 0$) can also be studied as a function of different physical quantities (T , p , concentrations, magnetic field, etc.) and the corresponding graphical representation is called a phase diagram. Phase diagrams of two-component systems at constant pressure (binary phase diagram) are particularly important for understanding crystal growth.

These are often determined experimentally, but can also be calculated/simulated from the Gibbs free enthalpies (further reading: Kaufman and Bernstein, 1970). As a simple example of a binary phase diagram, the Si/Ge system is shown in Fig. 3a, a system with complete miscibility in the solid and in the liquid. The bold solid lines represent the phase boundaries indicating where the liquid and the solid SiGe coexist. While the pure substances Si and Ge have a defined melting point, SiGe has a broad temperature region (A to B) where the solid and the liquid coexist. A melt with a certain SiGe composition—as indicated by the dashed line in Fig. 3a starts crystallizing at temperature T_A and composition A, enriches in Ge during cool down, and fully crystallizes at T_B with composition B (Zinkevich et al., 2006). This has severe implications for crystal growth. While pure Si and Ge crystals are grown by the Czochralski method (Cz) by keeping the melting point constant and temperature gradients small, growing SiGe is a big challenge. Cz-growth is only feasible close to the pure substances; other methods must be used for high concentrations, such as e.g. epitaxy method (far from equilibrium).

Generally, phase diagrams are more complex. As an example, the $\beta\text{-Ga}_2\text{O}_3/\text{La}_2\text{O}_3$ system is shown in Fig. 3b. Several congruently melting, intermediate, stable phases and eutectics can be observed. In view of this, finding a suitable crystal growth method for the desired crystal usually starts with studying phase diagrams.

Kinetics

Thermodynamic considerations are very powerful in describing which phases are stable, but they do not explain how these phase transitions occur. Certain mechanisms might be hindered or not given enough time to take place, and therefore metastable states might dominate in practical applications. Kinetic theories look at how a crystal actually grows atom by atom. Therefore, kinetic theories are essential for understanding crystal growth, and have to be considered for reliable insights (Nancollas and Purdie, 1964).

A simple kinetic theory of crystal growth was first described by Kossel (1927) and Stranski (1928). It is assumed that the crystal surface does not deviate significantly from bulk and that potential sites for crystal growth units arriving at the crystal surface to attach are the bulk lattice sites, which are the energetically favorable. Consequently, they describe the growth by giving different desorption energies to different types of lattice sites (see Fig. 4) (Derby, 2005). With the Kossel-Stranski model it was possible to predict the stability of facets in crystals.

The growth of a perfect crystal requires the nucleation of the crystal growth units on a perfect crystal surface (Gibbs, 1928). This monolayer nucleus would then laterally grow towards the edge of the crystal face. The nucleation process is generally slower than the lateral growth and transport mechanisms, and should therefore be the rate determining step. This picture would predict a critical supersaturation/supercooling below which no crystal growth can take place, which has not been observed in several systems (Volmer and Schultze, 1931). Frank (1949) could describe this discrepancy by considering imperfect, real crystals containing dislocations. He showed that, for example, a screw dislocation can serve as a source for perpetual steps and further on as nucleation sites for lateral monolayer growth, avoiding the need for nucleation, as shown in Fig. 5a and b. These growth spirals originating from dislocations could be observed in many substances as shown in Fig. 5c (Seiss et al., 2013; Shtukenberg et al., 2013; Fan et al., 2018). It has been shown on nearly-perfect crystals that both the nucleation mechanism and the dislocation mechanism proposed by Frank can occur, even on different crystal facets of the same single crystal (Sears, 1956).

Kinetic theories can also be applied to describe the growth habit that results from crystal growth.

When there are sufficient steps to nucleate on, growth is limited by the transport of crystal growth units to these steps. In this case, the fastest growing facet outgrows and the slowest growing facets dominants, resulting in a highly-faceted crystal habit. On the other hand, when nucleation of new layers on the surface dominates, which is the case when the crystallization driving force is high, then the surface tends to be atomically rough, referred to as kinetic roughening. It plays a key role in crystal growth from the vapor phase (e.g. molecular beam epitaxy) and is generally undesirable when atomically flat interfaces are desired (Wolf, 1991). In summary, all

Fig. 5 Sketch of a screw dislocation emerging normal at the crystal surface as: (a) continuous deformation of the plane, (b) in a block model, and (c) an image of a real growth spiral arising from a screw dislocation. Based on Frank FC (1949) The influence of dislocations on crystal growth. *Discussions of the Faraday Society* 5: 48–54.; Shtukenberg AG et al. (2013) Illusory spirals and loops in crystal growth. *Proceedings of the National Academy of Sciences* 110: 17195–17198; reprinted with permission of RCS.

these theories offer insights into the mechanism of crystal growth, but the actual crystal growth process is much more complex. Crystal growth is a field of active research and numerical modeling and simulation are becoming increasingly important.

Crystal growth modeling

The crystal growth processes involve a wide variety of physical and chemical phenomena taking place over a wide range of length and time scales, as shown in Fig. 6. At the lowest microscopic scale are ab initio molecular dynamics (MD) methods dealing with atomic behavior, while on the macroscopic scale are continuum methods. The latter provide a deeper insight into the various transport phenomena (e.g. momentum, heat, and mass transport) and thermoelastic stress occurring during the crystal growth and their relationships to crystal growth process parameters. The gained knowledge is essential for process development, scale up, optimization and control.

The pioneer attempt to model crystal growth processes on the macro scale goes back to the '70s and the work of Kobayashi and Arizumi (1970a, 1970b) and Kobayashi (1978). They used a simple steady state 2D axisymmetric model to describe the Czochralski growth of germanium and garnets (Yttrium Aluminium Garnet (YAG) and Gadolinium Gallium Garnet (GGG)). Within the last 5 decades, numerous studies have been devoted to the modeling of various crystal growth processes for various materials at the large-scale, as extensively reviewed in e.g., Derby and Yeckel (2004), Derby et al. (2007), Müller and Ostrogorsky (1994), Yeckel and Derby (2003), Polezhaev (2003), Szmyd and Suzuki (2000) and Rudolph (2010a, 2010b).

The models became more complex and closer to the real crystal growth setups, handling 3D geometries, transient processes, chemical reactions, magnetic and electric fields, etc.

Continuum methods

The transport of heat, mass, and momentum is especially important in bulk crystal growth processes in all solids (crystal and furnace parts) and fluids (melt, solution phase in the solution growth and gas atmosphere) present in the furnace.

For incompressible (density = constant), Newtonian fluids, flows are described by mass conservation equation:

$$\nabla \cdot \vec{u} = 0 \quad (3)$$

where $\vec{u}$ is the fluid velocity.

Governing equations for conservation of moment (Naver-Stokes equation) have the form:

$$\rho \frac{D\vec{u}}{Dt} = \rho \left(\frac{\partial \vec{u}}{\partial t} + (\vec{u} \cdot \nabla) \vec{u} \right) = -\nabla p + \mu \nabla^2 \vec{u} - \rho_{ref} \vec{g} (\alpha(T - T_{ref}) + \alpha_c(c_i - c_{i,ref})) + \vec{F} \quad (4)$$

The following notation was used: D/Dt is the substantial derivate, t is the time, ρ is the fluid density, p is the pressure, μ is the dynamic viscosity, $\vec{g}$ is the gravitational vector, T is the fluid temperature, c_i is the molar concentration of solute i , α is the coefficient of thermal volumetric expansion, α_c is the coefficient of concentrational volumetric expansion and $\vec{F}$ is the volumetric body force acting in the fluid. The notation ref. is used for the characteristic value in the domain.

If magnetic field is applied on the fluid, $\vec{F}$ will be equal Lorentz force density $\vec{F}_L$, defined in:

$$\vec{F}_L = \vec{j} \times \vec{B} = \sigma_{el} (\vec{E} + (\vec{u} \times \vec{B})) \times \vec{B} \quad (5)$$

where $\vec{j}$ is the current density, $\vec{B}$ is the magnetic induction, σ_{el} is the electrical conductivity and $\vec{E}$ is the electric field strength.

Fig. 6 Different modeling approaches in crystal growth for various time and length scales. Based on Derby JJ et al. (2007) Large-Scale Numerical Modeling of Melt and Solution Crystal Growth. in: Skowronski M, DeYoreo JJ, Wang CA (Eds.). *Perspectives on Inorganic, Organic, and Biological Crystal Growth: From Fundamentals to Applications*, 13th International Summer School on Crystal Growth.

The Lorentz force density can be derived from the solution of following equations: (i) Magnetic induction equation:

$$\frac{\partial \vec{B}}{\partial t} = \frac{1}{\mu_r \cdot \sigma_{el}} \left(\nabla^2 \vec{B} \right) + \left(\nabla \times \left(\vec{u} \times \vec{B} \right) \right) \quad (6)$$

where μ_r is the magnetic permeability; (ii) Gauss law for magnetism:

$$\nabla \cdot \vec{B} = 0 \quad (7)$$

$$\nabla \cdot \vec{E} = 0 \quad (8)$$

and (iii) Maxwell-Faraday equation:

$$\nabla \times \vec{E} = -\frac{\partial \vec{B}}{\partial t} \quad (9)$$

$$\nabla \times \vec{H} = \vec{j} \quad (10)$$

where H is the magnetic field strength.

Governing equation for conservation of energy has a form:

$$\rho c_p \frac{DT}{Dt} = \rho c_p \left(\frac{\partial T}{\partial t} + \left(\vec{u} \cdot \nabla \right) T \right) = \lambda \nabla^2 T + A \quad (11)$$

where c_p is the heat capacity, λ is the heat conductivity and A is the general heat source in the fluid. If heat is generated by a chemical reaction, the heat source A has the form:

$$A = \Delta H_i \cdot R_i \quad (12)$$

where ΔH_i is the reaction enthalpy and R_i is the chemical reaction rate for the component i .

For multicomponent systems, the species conservation equation is given in a form:

$$\frac{Dc_i}{Dt} = \frac{\partial c_i}{\partial t} + \left(\vec{u} \cdot \nabla \right) c_i = D_i \nabla^2 c_i + R_i \quad (13)$$

where D_i is the molar diffusion coefficient for the species i . In the simplest case, the chemical reaction rate R_i is directly proportional to the concentration of the component c_i aka the reaction rate is of the first order:

$$R_i = -k \cdot c_i = -k_0 e^{-\frac{E_A}{RT}} \cdot c_i \quad (14)$$

where k is the reaction rate constant defined via an Arrhenius equation and E_A is the activation energy for the chemical reaction.

In the crystal growth furnace, the field distribution in each body, i.e. in each domain, is governed by the differential equations described above. To be able to solve them, along the domain boundaries, boundary conditions must be imposed. In the case of transient simulations, also initial conditions for the whole domain must be defined. There are four types of boundary conditions (BC): (i) Dirichlet BC with specified variables u , T or c_i ; (ii) Neumann BC with specified heat or mass fluxes; (iii) Robin BC with a weighted combination of Dirichlet and Neumann BCs and (iv) radiation BC (a kind of Neumann BC with non-linear temperature dependence T^4).

Along the moving boundary of the crystallization front, the Stefan and isothermal conditions have to be satisfied:

$$\begin{aligned} [(-\lambda_l \nabla T)_l + (\lambda_s \nabla T)_s] \cdot \vec{n}_{s,l} &= \Delta H_s r_{\text{growth}} \\ T &= T_m \end{aligned} \quad (15)$$

where ΔH_s is the latent heat of solidification, r_{growth} is the crystal growth rate, T_m is the melting temperature, and n is the vector orthogonal to the crystallization front.

Governing equations can be derived for any coordinate system (e.g. rectangular (Cartesian), cylindrical or spherical), although the most convenient form is usually assumed for the sake of simplicity, especially when defining the boundary conditions.

A cylindrical coordinate system is commonly used in the bulk crystal growth techniques with axisymmetric crystals, such as Czochralski (Cz), Floating Zone (Fz), and Vertical Gradient Freeze (VGF). In directional solidification (DS), where the crystal grows in a rectangular crucible, the Cartesian coordinate system is the better choice (Fig. 7).

Governing conservation equations can be transformed into a dimensionless form, which reveals the governing dimensionless groups, allows identification of significant and insignificant terms, and facilitates scaling of the process.

The dimensionless form of the conservation equations are given below:

$$\frac{D \vec{u}^*}{Dt^*} = -\nabla^* p^* + \frac{1}{Re} \nabla^{*2} \vec{u}^* + \frac{Gr}{Re^2} T^* + \frac{Gr_c}{Re^2} c_i^* + \frac{Ha^2}{Re} \left(\vec{j}^* \times \vec{B}^* \right) \quad (16)$$

$$\frac{DT^*}{Dt^*} = \frac{1}{Re \cdot Pr} \nabla^{*2} T^* + A^* \quad (17)$$

$$\frac{Dc^*}{Dt^*} = \frac{1}{Re \cdot Sc} \nabla^{*2} c^* + R^* \quad (18)$$

$$\frac{D\vec{B}^*}{Dt^*} = \frac{1}{Re_m} \nabla^{*2} \vec{B}^* + \nabla \times \left(\vec{u}^* \times \vec{B}^* \right) \quad (19)$$

Cartesian coordinates x, y, z can be made dimensionless (notation $*$) by dividing them with the characteristic length scale L of the geometry, e.g. diameter or height of the grown material:

$$x^* = \frac{x}{L}; y^* = \frac{y}{L}; z^* = \frac{z}{L} \quad (20)$$

In the same way, other variables can be made dimensionless by using their characteristic value (notation ref), mean value (notation av) or their characteristic difference value (notation $\Delta_{T,ref}$ for temperature difference) in the domain, e.g.:

$$\vec{u}^* = \frac{\vec{u}}{u_{av}} \quad (21)$$

Fig. 7 The most popular bulk crystal growth techniques: (a) Czochralski, (b) Floating zone, (c) Directional Solidification and (d) Vertical Gradient Freeze.

$$T^* = \frac{T - T_{ref}}{\Delta T_{ref}} \quad (22)$$

$$c_i^* = \frac{c_i}{c_{ref}} \quad (23)$$

$$t^* = \frac{t \cdot u_{av}}{L} \quad (24)$$

$$p^* = \frac{p}{\rho \cdot u_{av}} \quad (25)$$

$$\nabla^* = L \cdot \nabla \quad (26)$$

$$\nabla^{2*} = L^2 \cdot \nabla^2 \quad (27)$$

$$B^* = \frac{B}{B_{ref}} \quad (28)$$

$$H^* = \frac{H}{H_{ref}} \quad (29)$$

$$J^* = \frac{J}{J_{ref}} \quad (30)$$

The solutions of non-dimensional equations depend on the coefficients that appear in them, known as dimensionless numbers. Their definitions and detailed descriptions are given in Table 1.

The material properties and Pr number of several important melts for electronic industry are summarized in Table 2. The data show the difference in Pr numbers of 4 orders of magnitude.

Small values of the Pr number, i.e. $Pr \ll 1$, means the thermal diffusivity dominates, whereas with $Pr \gg 1$, the momentum diffusivity dominates. In other words, Pr number provides information on the relative thicknesses of the momentum and thermal boundary layers. Similarly, the Schmidt Sc number provides information on the relative thickness of the momentum and concentration boundary layers.

In buoyancy driven flows that are common in crystal growth, the values of Gr and Pr numbers (and derived Ra numbers) determine the flow regime, as shown in Fig. 8. Knowing the onset of turbulence is of particular importance for process stability and control.

Table 1 The most important dimensionless numbers in crystal growth.

Reynolds	Ratio of inertia to viscous forces	$Re = \frac{u_{av} \cdot L \cdot \rho}{\mu}$
Reynolds (magnetic)	Ratio of convection to diffusion in magnetic field	$Re_m = u_{av} \cdot L \cdot \sigma_{el} \cdot \mu_0$
Prandtl	Ratio of molecular momentum and thermal diffusivities	$Pr = \frac{\mu \cdot c_p}{\lambda}$
Grashof	Ratio of buoyancy to viscous forces	$Gr = \frac{\alpha \cdot g \cdot \Delta T_{ref} \cdot L^3}{\nu^2}$
Schmidt	Ratio of molecular momentum and mass diffusivities	$Sc = \frac{\nu}{D}$
Hartmann	Ratio of electromagnetic force to the viscous force	$Ha = B \cdot L \cdot \left(\frac{\sigma}{\mu}\right)^{0.5}$
Rayleigh	A measure of the vigor of convection	$Ra = Gr \cdot Pr$
Péclet	Ratio of heat transfer by convection to conduction	$Pe = Re \cdot Pr$
Péclet (mass transfer)	Ratio of bulk mass transfer to diffusive mass transfer	$Pe_D = Re \cdot Sc$

Notation: ν is the kinematic viscosity ($\nu = \mu \rho^{-1}$); μ_0 is the magnetic permeability of the free space.

Table 2 Properties of the relevant melts for electronic and solar industry (Miller and Ostrogorsky, 1994; Rudolph and Mühlberg, 1993; Miller et al., 2017; Dobrovinskaya et al., 2008).

Fig. 8 Rayleigh-Prandtl regime diagram for steady, transitional, time-dependent and turbulent buoyancy driven flows. Based on Krishnamurti R (1973) Some further studies on the transition to turbulent convection. *Journal of Fluid Mechanics* 60: 285–303.

In the case of Cz-Si growth, for melt height $L = 0.2$ m and axial $\Delta T = 50$ K, the key dimensionless numbers have values $Gr = 4.2 \times 10^9$, $Pr = 0.014$ and $Ra = 5.9 \times 10^7$. According to the Rayleigh-Prandtl diagram (Fig. 8), the flow regime is turbulent. In the pure buoyancy regime, the Gr number of order 1×10^9 is the universal criterion for the transition to turbulence (Bejan and Lage, 1990; Krishnamurti, 1973).

Relative importance of buoyancy with respect to forced convection is determined by the ratio of Gr and Re^2 numbers.

Buoyancy convection is negligible if the following criterion is met:

$$\frac{Gr}{Re^2} < 0.1 \quad (31)$$

Forced convection is negligible if:

$$\frac{Gr}{Re^2} > 10 \quad (32)$$

Both convection types (buoyancy and forced) are important in the range:

$$0.1 < \frac{Gr}{Re^2} < 10 \quad (33)$$

Again, in case of previously mentioned Cz-Si growth with $Gr \sim 1 \times 10^9$, transition between solely buoyancy to mixed regime (Eq. 31) occurs at $Re = 1 \times 10^4$, while transition from mixed to pure forced convection regime (Eq. 32) occurs at $Re = 1 \times 10^5$.

Besides aiding in understanding the growth phenomena, dimensionless numbers can also strongly facilitate the scale up of the process and equipment. The importance of the latter is directly related with the common challenge in the crystal growth to improve process economy while preserving the crystal quality. For reaching that goal, higher crystallization yields and upscaled crystal sizes are beneficial. The fundamental approach to scale up is achieved by applying the principle of similitude (Marphy, 1950; Kline, 1986) between the small scale and the commercial equipment. That means keeping the characteristic dimensionless groups that characterize the process phenomena constant during scale up. To achieve similitude between two crystal growth processes and equipment, all criteria must be fulfilled: geometric, kinematic and dynamic similarity.

Process engineering

Computational fluid dynamics (CFD) is a traditional tool for solving the governing differential equations by replacing them with approximate algebraic equations at discrete points of the solution domain. Obtained velocity, concentration, pressure and temperature fields help understanding the key process steps and process parameters determining the complex, highly interrelated physical phenomena in crystal growth. The bottleneck of this approach is the fact that CFD simulations, especially in 3D and with transient character are laborious, expensive and time consuming, without the ability to generalize. The prediction accuracy of CFD simulations is highly dependent on the availability and accuracy of material data over a wide temperature range, especially when anisotropy and radiation are present in solids. Oversimplified domain geometry (e.g. choosing the 2D model for non-axisymmetric geometry), neglecting turbulence and the transient process nature lead to poor quality predictions, especially at industrial scale and for the growth of novel crystalline materials.

One of the most exciting novel tools that has recently appeared in the field of crystal growth is machine learning (ML). This collection of statistical methods has a great potential in acceleration of fundamental and applied research, particularly with respect

of process and equipment multi-objective optimization, process control, generalization and interpretability of the results. Also, ML methods have one important advantage to CFD models, as they can be trained on both experimental and numerical data pools. They don't require explicitly described knowledge of physical laws underlying the data nor the material data of the species present in the growth equipment, that knowledge is implicitly contained in the training data.

In the last few years, ML applications are mushrooming in all fields of crystal growth and on all scales, from bulk to epitaxial growth, from numerical simulations to experiments and from atomic to macro scale (Kutsukake et al., 2020, 2022; Dropka and Holena, 2017; Dropka et al., 2021a; Dropka et al., 2021b; Chou et al., 2022; Qi et al., 2020; Tsunooka et al., 2018; Dang et al., 2019, 2021; Asadian et al., 2009; Yu et al., 2021; Schimmel et al., 2021; Takehara et al., 2020; Boucetta et al., 2019; Osada et al., 2020).

The first measurable success is mirrored in the fact that enlargement of SiC wafer size from 1 in. to 6 in. was reached in less than 3 years with a support of machine learning, while it took 40 years to enlarge Si wafers diameter from 1 in. to 12 in. by common numerical and experimental approaches (Dold, 2015).

There are many available ML algorithms e.g., artificial neural network (ANN), Decision Trees (DTs), Random Forest etc. The guiding principles of choice depend mainly on the volume and quality of input data, type of output, targeted prediction accuracy, and required interpretability of results.

The ANN method is the most widely used ML technique in general and also in crystal growth. Therefore, the basic principles will be shortly explained.

This method resembles a simple concept of human brain and is particularly powerful when correlating a very large number of variables with highly non-linear dependences (Rojas, 1996). ANNs are capable pointwise to approximate smooth functions to any degree of accuracy.

An ANN is defined principally by its architecture, i.e. a set of artificial neurons and connections between them. The simplest kind of neural network is a multi-layer perceptron network (Fig. 9). The neurons are usually organized into layers: an input layer, one or more hidden layers and an output layer. Each neuron performs as a computational unit that receives inputs x_i , multiplies them by weights w_i and then uses the sum of such weighted inputs as the argument for a nonlinear function (a common choice is a logistic sigmoidal function $f(x, w)$ (Eq. 34)), which activates neuron and yields the final output y_j . The whole ANN receives inputs by neurons in the first layer, and obtains output by the neurons in the last layer, i.e. the neurons are interconnected in a feed-forward way.

$$y_j = f(x, w) = \frac{1}{1 + e^{-\left(\sum_{i=1}^n (w_{ji} x_i + b_i)\right)}} \quad (34)$$

By adjusting the weights $\Delta w_{j,i}$ of connections and biases b_i of artificial neurons (aka ANN training), the targeted output y_j can be obtained for a specific combination of inputs x_i . The aim of ANN training is to adjust the weights and biases to minimize some kind of error E (e.g. the sum of squared differences between the outputs y_j of the network and the desired output o_j over all the neurons in the output layer) measured on the network.

$$E(x, w, o) = \sum_j (y_j - o_j)^2 \quad (35)$$

The weights can be adjusted using various methods, e.g. the method of gradient descent with constant learning rate:

$$\Delta w_{j,i} = -\eta \frac{\partial E}{\partial w_{j,i}} \quad (36)$$

Before ANN training, it is necessary to choose the ANN architecture, the activation function and the training method. A comparison of different ANN architectures is usually estimated by the k -fold cross validation method (Rojas, 1996). It starts by dividing the training set into k subsets. For each ANN architecture, the training is performed k times, each time using one of the subsets as the

Fig. 9 Example of a feed forward multi-layer perceptron artificial neural network: (a) neuron, (b) architecture.

validation set and the remaining subsets as the training set. In the next step, the architecture is selected that had the smallest error averaged over the validation sets from the k runs. Finally, the ANN model with this architecture is used to train on all the data. After being trained, the ANN model reflects the relationship between the input and output of the system.

An example of ANN-based real-time prediction of interstitial oxygen in Cz-Si growth as a function of process parameters, age of hot-zone parts, monitored temperature, and crystal diameter is given in (Kutsukake et al., 2020) (Fig. 10). ANN was trained on industrial experimental crystal growth data. Accurate, real-time prediction of various key process parameters and finally their optimization was the topic of many studies.

If the understanding of how some crystal growth parameters contribute to the optimization goal, aka the interpretability of the results, DT is a better choice. Once “sensitive parameters” have been identified, an optimization is easy and straightforward.

The DT method works in the following way: each node in the tree represents a variable x_i from the input datasets, each branch a decision and each leaf at the end of a branch the corresponding output value y_i . The decision process aka splitting starts from the top root node downwards through the tree until a bottom leaf is reached which contains the result. The splits are made in such a way that the sum of squared errors with respect to the average values of the y_i in the above subsets is minimal.

An example of Classification Tree (type of DT) analysis of the process parameters influencing interface deflection in VGF-GaAs growth is given in Fig. 11 (Dropka et al., 2021a, 2021b). Orange branches correspond to the growth recipes where leaf nodes have a convex shape of s/l interface ($y_2 \leq 0$, denoted as “-”). The results revealed x_4 (the power of the upper side heater), followed by x_5 (the power of the lower side heater) and x_1 (the growth rate) as the most decisive inputs and the range of their values for the favorable interface shape. Their significance decreases in the order mentioned above.

In this chapter, we presented the different approaches to solve macroscale continuum models from CFD simulations, dimensional analysis based on dimensionless numbers to machine learning techniques. In our opinion, the latter are capable of significantly accelerating both fundamental and applied research and will certainly shape crystal growth in the future.

Crystal growth analysis

Defects

Crystal defects are unavoidable imperfections in the periodic crystal lattice in real crystalline solids (Rudolph, 2007; Rudolph, 2010a, 2010b; Klapper and Rudolph, 2015; Hurle and Rudolph, 2004).

Crystal defects are traditionally classified after their dimensionality that may vary from 0 to 3 (Fig. 12). The 0-dimensional are point defects which include vacancies, interstitial atoms, substitutional atoms, and antisites (in compounds). If substitutional atoms are incorporated intentionally, they are called dopants. If they enter the crystal structure by accident, they are building residual impurities. The 1-dimensional are line defects that include all kinds of dislocations, i.e. screw and edge dislocations, mixed dislocations, partial dislocations, and dislocation loops. The 2-dimensional planar defects are, e.g. grain boundaries, phase boundaries, facets, stacking faults and twins. The 3-dimensional are bulk defects, such as precipitates (second phase particles), inclusions (foreign particles at the crystallization front) and microvoids (intrinsic vacancy conglomerates).

Alternatively, the crystal defects can be classified according to their origin. For example, they can come from: the feedstock, the substrate, and/or during different process steps: furnace heating up, stationary growth, transient growth, cooling down and further crystal processing.

Fig. 10 Example of prediction of oxygen concentration in Cz-Si ingot as a function of process parameters using ANN model trained on experimental crystal growth data. The derived ANN architecture includes 3 layers with 47 neurons, 43 inputs and 1 output. Based on Kutsukake K et al. (2020) Real-time prediction of interstitial oxygen concentration in Czochralski silicon using machine learning. *Applied Physics Express* 13: 125502.

Based on Rudolph P (2010) Transport phenomena of crystal growth-heat and mass transfer. *AIP Conference Proceedings* 107: 1270.

In addition, the defects can be classified according to their influence on the structural, chemical, electronic and radiation properties of the crystal.

In the case of Si, which is the predominant semiconductor material for the photovoltaics and electronic industry, common defects are: (i) self-interstitial point defects, which can act as carrier traps, (ii) dislocation and dislocation-loop line defects, which can reduce the minority carrier lifetime in solar cells and lead to eddy circuits and shorts in microelectronics, (iii) grain boundaries

planar defects that may cause impurity gettering and consequently reduction in solar cell efficiency, and finally (iv) microvoid bulk defects in metal-oxide-semiconductor (MOS) transistors can lead to degradation of the gate oxide.

In order to ensure high quality of the grown crystals and to meet different application requirements, controlling the formation of crystal defects aka crystal defects engineering is crucial. There are two feasible approaches to tackle this topic: (i) in situ control of the crystal growth process and (ii) post-annealing of the bulk crystals or their wafers. The first approach can be achieved by growing crystal within “defect-free regime” defined by Voronkov criteria (Voronkov, 1982):

$$1 \times 10^{-3} < \frac{r_{\text{growth}}}{\text{grad}T} < 2 \times 10^{-3} \frac{\text{cm}^2}{\text{K} \cdot \text{min}} \quad (37)$$

using very low pulling velocities of about 0.5 mm/min and low cooling rates. The second approach is coupled with: (i) growing crystal with high pulling and high cooling rates followed by annealing of wafer and (ii) high pulling and high cooling rates with annealing of wafers and deposition of epi-layers as proposed by Dornberger et al. (2001). The latter approach is the most cost-effective.

In the growth of crystal compounds, defect control can also be achieved by coupling with compositional control via a fixed temperature vapor source of the volatile component. The vapor-pressure controlled Czochralski growth of GaAs crystals is a typical example of this approach (Neubert et al., 2008).

Segregation

Solutes generally have a different equilibrium solubility in the crystal and the melt. Segregation arises from this difference. Segregation describes the enrichment of solute atoms in the crystal or the melt during crystallization. These solute atoms can be intentional, as in the case of doping semiconductors, or unintentional, in the form of impurities. Understanding the distribution of solute atoms, and hence segregation arising from crystal growth is essential for achieving homogenous doping or crystal purification.

A key concept for studying segregation is the segregation coefficient k , which is defined as the ratio of the solute concentration in the crystal and the melt. Its equilibrium value k_0 can be determined from an equilibrium phase diagram. A sketch of a phase diagram of a melting point reducing solute in a crystal/melt system can be seen in Fig. 13a. The melting temperature of the pure crystal is indicated by T_m , and the equilibrium solute concentration in the crystal and the melt is indicated by C_s and C_L , respectively. The liquidus and solidus line can be approximated by lines, since relevant solute concentrations are generally small (compare to the left side of the phase diagram in Fig. 3a). In this case, the k_0 is a constant and determined by $k_0 = C_s/C_L$. For deviations from this linear approximation (for instance for higher solute concentrations), k_0 is temperature-dependent. In the case of a melting point reducing solute, k_0 is <1 (as in Fig. 13a), in the case of a melting point increasing solute it is >1 , and no segregation occurs in the case of $k_0 = 1$. For most solutes, the segregation coefficient is <1 , which can be qualitatively understood by the fact that it is energetically less favorable for solute atoms to be incorporated in a crystal (resulting in a crystal defect) than being dissolved in a melt. For instance, segregation coefficients of most transition metals in Si are $<10^{-3}$, and the segregation coefficients

Fig. 13 The solidification of the melt with low concentration of solute: (a) simplified part of the phase diagram, (b) axial segregation of solute, (c) constitutional supercooling conditions in temperature-distance-from-the-interface diagram. Notation: T_L, T_S, T_m, T_1, T_2 are liquidus, solidus, melting and two different cases of actual temperatures in the melt; C_L, C_S are solute concentrations at liquidus and solidus curves.

for typical dopants such as P or As are around 10^{-1} (Johnston et al., 2012). Hence, from here on in this section it is assumed that $k < 1$, but all statements can be translated to the $k > 1$ case.

For real crystal growth applications, deviations from the equilibrium segregation coefficient can be observed. The impact of the crystallization conditions on the segregation coefficient was first described in Burton et al. (1953) within the BPS model (named after Burton, Prim, and Slichter). Deviations from equilibrium lead to reduced segregation and hence their effective segregation coefficient k_{eff} is closer to unity than k_0 . In the BPS model one assumes that the solute atoms get rejected after at the propagating crystal/melt interface that they can diffuse into the melt. Consequently, a boundary layer with increased solute concentration builds up, which results in:

$$k_{\text{eff}} = \frac{k_0}{k_0 + (1 - k_0) \exp\left(-\frac{r_{\text{growth}} \cdot \delta}{D}\right)} \quad (38)$$

where r_{growth} is the propagation velocity of the crystal/melt interface (growth velocity), δ is the thickness of the boundary layer, and D is the diffusion coefficient of the solute atoms in the melt. For a small $\frac{r_{\text{growth}} \cdot \delta}{D}$ the effective segregation coefficient approaches k_0 , which is achieved by a small growth velocity, a narrow boundary layer thickness (e.g. by stirring), and a high diffusivity. For a large $\frac{r_{\text{growth}} \cdot \delta}{D}$, the effective segregation coefficient converges to 1. For homogenous doping of a crystal, one wants achieve a low segregation ($k_{\text{eff}} \rightarrow 1$), while for crystal purification (as for instance in zone refining) a high segregation ($k_{\text{eff}} \rightarrow k_0$) is preferred.

The solute distribution of a growing crystal can be understood by the concept of normal freezing (Pfann, 1952). Here, the crystal grows directionally into the melt, as depicted in Fig. 14. In this model transport of solute atom (e.g. via diffusion) in the melt is instantaneous, while neglected in the crystal. This is a good approximation for crystal growth, since transport mechanisms in the melt are fast, and diffusion mechanisms in the crystal are slow relative to growth time scales. The resulting solute concentration as a function of solidified fraction m is called the Scheil equation (Scheil, 1942) and is:

$$C_S = k \cdot C_0 (1 - m)^{k-1} \quad (39)$$

where C_0 is initial solute concentration in the melt.

The presented models represent a starting point to study segregation in crystal growth. The theories here had several shortcomings, as the treatment of transport phenomena in the crystal and the melt was simplified, only one-dimensional problems were considered, and most importantly the systems were closed systems (no solute atoms from or to the environment). In real growth processes more complicated considerations often have to be taken into account and numerical methods are required.

Morphological instability

Under certain crystal growth conditions, when the solutes (e.g. impurities or low concentration dopants) are not homogeneously mixed in the melt and when the solute boundary layer is well developed, the solid-liquid interface can become morphologically unstable due to the constitutional supercooling effect (Fig. 13) (Wenzl et al., 1993).

Supercooled zones in melts are observed when the liquidus temperature gradient at the solid-liquid interface is higher than the actual temperature gradient in the melt. The region where the melt is constitutionally supercooled is marked by the shaded area in Fig. 13c. In this situation the interface becomes morphologically unstable because any fluctuation forms a protuberance of the interface. Depending on the intensity of supercooling, interface shape may become wavy, cellular and even dendritic (Fig. 15) (Warren and Langer, 1993).

The constitutional supercooling is an adverse phenomenon that leads to polycrystallinity and limits crystal growth applications.

Fig. 14 Schematic solute concentration distribution of normal freezing of a melt.

Fig. 15 Interface shapes for different intensity of constitutional supercooling: (a) wavy for a weak, (b) cellular for moderate and (c) dendritic interface for a strong supercooling. Based on Warren JA, Langer J (1993) Prediction of dendritic spacings in a directional-solidification experiment. *Physical Review E* 47: 2702; reprinted with permission of APS.

The first theoretical studies of constitutional supercooling were published by Tiller et al. (1953) and Hurle (1961). They derived theoretically the condition for the preservation of morphological stability of the interface, i.e. a prevention of constitutional supercooling.

The onset of the constitutional supercooling is determined by Mullins-Sekerka criterion (Mullins and Sekerka, 1964):

$$\frac{dT_L}{dz} < \frac{mc_0(1-k)r_{growth}}{kD} \quad (40)$$

where m is a slope of liquidus curve on the phase diagram (Fig. 13a) and k is a segregation coefficient (a ratio of solute concentration in the solid to solute concentration in the melt). The slope m can be estimated from the equation of Thurmond and Kowalchik (1960):

$$m = \frac{T_m^2 \cdot R}{\Delta H_s} \quad (41)$$

$$k = \frac{C_s}{C_L} \quad (42)$$

where R is a gas constant ($R = 8.314 \text{ J mol}^{-1} \text{ K}^{-1}$).

From this equation it is obvious that the tendency for supercooling increases as: (i) temperature gradients decrease, (ii) diffusion coefficients increase, (iii) crystal growth rates increase and (iv) solidus/liquidus lines become steeper. Against this background, the following measures can be beneficial to morphological stability: (i) optimization of the hot zone in the furnace by adding heat shields to increase the temperature gradients, (ii) slowing down the growth process and (iii) increase the melt convection by external forces (e.g. Lorentz force, vibrational force, etc.).

Conclusion

The crystal growth processes with their complex physical and chemical phenomena, which extend over large length and time scales, can still not be described with a single theory, despite remarkable progress.

In the coming years, ML techniques are expected to significantly accelerate basic research in bulk crystal growth to achieve this goal. The main benefit lies in the prompt and precise ML predictive power, which is a stepping stone to explaining new theories and hypotheses when no convincing theory is available.

ML enables quantitative comparison of theoretical models based on their predictive success, which could reveal key factors relevant to their success and thus contribute to theory development. Moreover, ML can serve as a final trusted criterion for explaining novel theoretical models, free from human errors.

The clear game-changer in these endeavors will be the generation of open-source research data infrastructure in the future.

Abstract

Film and epitaxy growth form an essential part of engineering components, electronic and photonic devices. This chapter provides a summary of commonly used techniques both in research and for production scale. Examples of materials and applications are given for each of the techniques described. The chapter is broadly divided into two sections depending on the method to deliver elements onto the deposition surface. Vapor phase deposition includes evaporation techniques, chemical vapor deposition and energy assisted processes, covering a range of vapor pressures from atmospheric down to ultra-high vacuum. Solution based methods can be aqueous or solvent based and will normally entail a heterogeneous reaction to yield the required material onto the substrate. This includes chemical bath deposition, sol-gel and electrodeposition. Epitaxial growth is covered with descriptions of the commonly used techniques of molecular beam epitaxy (MBE), metal organic vapor phase epitaxy (MOVPE) and liquid phase epitaxy (LPE).

Key points

- Thin film deposition from the vapor using solid sources and chemical precursors.
- Background vapor pressure of the deposition chamber and significance of mean free path.
- The process of evaporation of solid sources by heating with electron beam, sputtering with plasma or laser ablation.
- The use of chemical precursors in the vapor in the form of organometallics and halides.
- The range of materials deposited as thin film coatings covers hard coatings, optical coatings and functional compound semiconductor films. 2D coatings such as graphene are also covered.

[☆]Change History: March 2023. SJC Irvine updated the text and added new Figures 1–11.

- Deposition from the liquid phase from chemical bath deposition, electrodeposition, sol-gel and liquid phase melts.
- 2D organic coatings using the Langmuir Blodgett deposition process.
- Epitaxial growth of compound semiconductors using either MBE, MOVPE or LPE.

Introduction

The growth of thin films covers an enormous range of applications from hard coatings on machine tool surfaces to semiconductor thin films for electronic and photonic devices. This chapter describes many of the commonly used thin film deposition methods and gives the reader an introduction to the different methods depending on the material being deposited and the application.

By way of introduction, the considerations for all deposition methods are as follows and shown schematically in Fig. 1.

- Substrate or surface to be coated.
- Environment for deposition, e.g. vacuum, chemical vapor, liquid etc.
- Source material.
- Transport of source material to the coating surface.
- Effluent, to include treatment of exhaust gases, removal of deposition material from deposition chamber.

These factors will be considered for each of the deposition methods, as appropriate. The next consideration is the crystalline form of the coating. Depending on the application, this can be amorphous, polycrystalline or single crystal. The latter is achieved through epitaxial growth where the substrate is a polished single crystal with the alignment of the lattice spacing between the substrate and the epitaxial film.

For each deposition method it is necessary to consider what drives the deposition process? Under equilibrium conditions there will be no film growth, so supersaturation needs to be created through a difference in chemical composition from the source to the film surface, or through changing parameters such as temperature or pressure. A combination of these deposition drivers is also possible. Alternatively, the loss of material from the surface can occur due to sublimation or chemical reaction, sometimes referred to as etch-back. Etch-back can sometimes be useful to present a clean surface prior to deposition. Again, this can be achieved through either chemical non-equilibrium or through changing physical parameters such as temperature and pressure.

The structural, morphology, electrical or optical properties of interest of a thin film depend on the application but in general, considerations will include: adhesion to the substrate, film thickness, film composition and film morphology. The latter is important since depending on the application a smooth or a rough surface is required. These can be controlled by the deposition process.

Physical vapor deposition

The process of physical vapor deposition (PVD) entails the evaporation of a solid source in a vacuum chamber and subsequent condensation onto a substrate surface. The quality of the vacuum depends on the material being deposited and the desired film properties but in general the aim is to minimize scattering from the ambient gas and avoid film contamination. This typically will require a vacuum of $<10^{-2}$ Pa (Haque et al., 2021). For very high purity applications such as for the deposition of semiconductor thin films in Molecular Beam Epitaxy (MBE) an Ultra-High Vacuum (UHV) is required ($<10^{-6}$ Pa). The choice of vacuum also determines the extent of molecular scattering between the source and substrate. For a molecular beam process the mean free path (MFP) needs to be much larger than the source to substrate distance. The MFP is determined by the following equation.

$$MFP = \frac{k_B T}{\sqrt{2} \pi d^2 p} \quad (1)$$

Fig. 1 Generic representation of thin film deposition.

Where k_B is Boltzman's constant, T is temperature of the gas in Kelvin, d is diameter of the molecule and p is the pressure of the gas. For example, 10^{-2} Pa will have a MFP of 50 cm and for 10^{-6} Pa it extends to 5 km. Differences between PVD methods are mostly associated with the method for evaporating the source material. Materials that are more volatile can be heated in a crucible while less volatile materials will require ion sputtering.

Evaporation

Thermal evaporation of elemental sources or compounds can be achieved, in the simplest case, by an electrically heated tungsten wire surrounding the source material. Examples of this approach would be in metallization of gold or silver for electrical contacts. Further refinements could entail the use of a crucible that is resistively heated. For crucible evaporation, the source (normally a metal) will need to be above its melting point. Compounds can also be evaporated from a melt or sublimed from the solid but can be more complex as the components will normally evaporate at a different rate, requiring an adjustment to the source composition or an additional elemental source of the less volatile component. In general, these approaches apply to relatively low melting point sources and most appropriate to single element evaporation. For higher melting point elements and compounds an electron beam source can be used (as illustrated in Fig. 2) which has the advantage of directly heating the source material without heating the crucible which can be water cooled to prevent damage. This method is commonly used for the deposition of optical coating materials where excellent uniformity of deposition can be achieved over multiple substrates. An example is the deposition of Ag/Al-doped ZnO reported by Sahu et al. (2007) which demonstrates the ability of e-beam evaporation to produce very controlled and uniform thicknesses of multiple optical layers. Other examples of e-beam evaporation are for anti-reflection coatings and optical filters (Sharma et al., 2018).

Sputtering

Sputtering is one of the most versatile thin film deposition techniques and can be used to deposit a very wide range of materials either as elements or compounds. The target material, instead of being heated, as with evaporation technique, is bombarded with ions from an inert gas discharge. The kinetic energy transfer causes the release of atomic species from the target surface. The target forms the cathode of a DC or AC plasma discharge. DC sputtering requires a conducting target whereas for AC sputtering the target can be conducting or insulating. The DC sputter process is also called "DC sputter diode discharge." This is the simplest form of sputter deposition and is shown schematically in Fig. 3. Characteristics of the operating conditions of a DC diode sputtering system are as follows.

Fig. 2 Schematic of electron beam heated evaporation source.

Fig. 3 Schematic of DC sputter discharge.

1. High operating voltages 2000–5000 V.
2. Narrow pressure range for the working gas pressure 2–4 Pa
3. Short ion mean free path (<1 cm)
4. Low mean energy for ions bombarding the cathode target (few eV)

The diode sputtering system can be adapted to sputter insulating targets by going to an AC field at RF frequencies.

The deposition rate in sputter deposition depends on the beam current density onto the target. Low-pressure glow discharge will typically have low current giving low deposition rates. It is also desirable to keep the ion current low near the substrate to avoid ion damage and sputtering of deposited material.

A magnetic field can be used to confine the ion current close to the cathode target yielding higher target current and keeping the ion density low near the substrate. This is achieved with magnetic coils or permanent magnets in the target holder as shown in Fig. 4. This is called magnetron sputtering. An example of radiofrequency (RF) magnetron sputtering is given by Yang et al. (2009) to deposit Al doped ZnO at room temperature for uniform transparent conducting oxides (TCOs). This is an example of the versatility of magnetron sputtering in depositing functional coating with good composition control, good optical transparency and control of electrical properties. The sputter targets were ZnO and Al_2O_3 . Having separate targets enables independent control of the flux from each target. The base pressure was 4×10^{-4} Pa. Under operating conditions the chamber pressure is increased to 0.1–1 Pa with the admittance of argon gas. Uniformity of the film can be optimized by a combination of adjusting the distance between sputter target and the substrate and then rotating the substrate.

Fig. 4 Schematic of magnetron sputtering.

Characteristics of magnetron sputtering systems are given by Gudmundsson (2020).

1. Secondary electrons confined by the magnetic field to sustain plasma close to the cathode.
2. High sputtering rates.
3. Operating pressure range 0.2–4 Pa.
4. Cathode voltage in range 300–700 V.
5. Discharge current density 4–60 mA cm⁻².
6. Deposition rate 20–200 nm min⁻¹.

Both DC and AC or pulsed electric fields can be used with magnetron sputtering. As with diode sputtering, the DC configuration is used for conducting targets and RF can be used for insulating targets such as the example given for ZnO deposition. A further variant on magnetron sputtering is to replace the argon gas with a reactive gas such as O₂, N₂ or CH₄ to enable “reactive magnetron sputtering.” The reactive gas species provides the sputtering ions and enables reaction both on the sputter target and at the substrate. This can be used to deposit compound films containing the reactive species such as oxides and nitrides. Further details reactive magnetron sputtering can be found in the review by Gudmundsson (2020).

Ion plating

Ion plating is a variant on physical vapor deposition processes where an ion beam is added to energize the surface. This has the advantages of sputter removal of impurities from the surface and providing heating to the surface to improve atom surface mobility. The sputter removal of surface impurities has the benefit of improving surface adhesion. However, the ion energies are sufficient that surface defects can be formed that may need to be subsequently annealed out. In an example given by Matthews and Teer (1980), ion assisted deposition of TiN, at temperatures below 600 °C, was used to prevent powder formation and enabled a high film density. Ion plating has been extensively used for producing hard, adherent coatings to steel. Kim et al. (2002) used a combination of DC magnetron sputtering and ion plating to produce “superhard” Ti-Si-N films onto steel. An arc cathode gun was used for the Ti source and a DC magnetron gun for the Si. Nitrogen was introduced as N₂ near the substrate. In this example we can see combinations of techniques being used to achieve the desired film composition and properties.

Thermal-spraying

The previous described PVD processes entail transport of atomic or molecular species to a substrate. Thermal spraying entails the transport of droplets. This can be used for rapid deposition of thick films, with high density, a number of micron thick. When the droplets hit the substrate, they spread out to form a coherent film. This implies that some kinetic energy is needed in the transport process. A variety of different sources can be used to achieve these conditions (Cinca and Guilemany, 2012).

1. High Velocity Oxygen Fuel (HVOF): an oxygen combustion flame heats specimen to high temperature which expands and sprays droplets onto the substrate.
2. Detonation gun: the oxygen – fuel gas supply is pulsed to give “explosive” bursts of sprayed droplets at higher velocity than for HVOF.
3. Flame spray: the powdered metal is melted in a combustion flame which expands and sprays the droplets.
4. Plasma spray: the source powder is injected into a low-voltage, high-current plasma that melts the powder. This is particularly advantages with refractory materials.
5. Cold gas spray: The metal powder is sprayed onto the target with high pressure gas and the film is subsequently annealed to form an alloy coating. For example, Ti-Al powder can be sprayed and then annealed at 630 °C to form TiAl₃/Al composite coating for aircraft components (Cinca and Guilemany, 2012).

Molecular beam epitaxy (MBE)

Molecular Beam Epitaxy entails producing very pure beams of atoms or molecules, directed at a single crystal substrate in ultra-high vacuum (10⁻⁸–10⁻⁹ Pa). In this method, the MFP is much greater than the chamber dimensions resulting in very low probability of molecular collisions between the source and substrate and low background contamination. Epitaxy is the process of growing a single crystal thin film where the crystal structure of the growing film is templated by a highly polished single crystal substrate. The simplest epitaxial approach is to use the same material for the substrate and the layer such as GaAs on GaAs. This ensures lattice matching but the electrical properties of the layer can be changed in the epitaxial film. Alternatively, a different composition film can be grown but maintaining lattice matching between the layer and the substrate as is the case with Al_xGa_{1-x}As on GaAs.

An MBE chamber is shown schematically in Fig. 5. The source materials are contained in accurately heated cells with a small hole for the vaporized molecules to escape. These cells are called Knudsen cells or K-cells. In front of each cell is a shutter so each beam can be turned on and off. Epitaxial films of precise thickness and composition can be grown by control of the sequencing of the K-cell shutters. MBE is suitable for high crystalline quality compound semiconductor multi-layer devices for high-speed electronics

Fig. 5 Schematic of an MBE chamber showing Knudsen effusion cells for the elemental sources, beamed onto the heated substrate.

Fig. 6 Reflection high-energy electron diffraction (RHEED) oscillations for GaAs (100) MBE where each oscillation corresponds exactly to one Ga + As monolayer (Neave et al., 1983). From Neave JH, Joyce BA, Dobson PJ, and Norton N (1983) Dynamics of film growth of GaAs by MBE from Rheed observations. *Applied Physics A* 31: 1–8.

and opto-electronic applications. The UHV chamber environment allows for in situ monitoring of the growth process using techniques such as RHEED (Reflection High Energy Electron Diffraction), AES (Auger Electron Spectroscopy) and XPS (X-ray Photo-electron Spectroscopy). For example, in pioneering work by Neave et al. (1983) the now familiar RHEED oscillation method was used to show that GaAs epitaxial films grew by a layer-by-layer process (Fig. 6). This is now a routine tool in research and production MBE systems to establish epitaxial growth and measure film thickness.

An example of recent MBE is the growth of InAs/GaAs quantum dot laser structures on silicon substrates (Kwoen et al., 2018). This illustrates a number of key advances including the hetero-epitaxy of $\text{Al}_x\text{Ga}_{1-x}\text{As}$ on silicon where there is a large lattice mismatch but the single crystal film is templated by the silicon substrate. This work also illustrates the formation of InAs quantum dots within the film, driven by a strain field. MBE is now a well-established research and production process for a wide range of compound semiconductor materials.

Chemical vapor deposition (CVD)

In PVD techniques the source is located inside the growth chamber and a vacuum is required to prevent reaction of the components in the vapor. Chemical Vapor Deposition (CVD) has the advantage of having the source materials outside of the reaction chamber and are carried in a gas flow to the growth chamber. The chemical precursors need to be stable at the temperature of delivery. This is either around ambient temperature or above ambient temperature in the case of less volatile precursors. The precursors must be stable at the storage temperature and preferably, liquids but solids can be sublimed or dissolved into a suitable solvent. The method of transport is to bubble a fixed flow rate of a carrier gas such as nitrogen through the precursor and then mix with other precursors and a dilution gas flow through a network of pipes. For example, to deposit a film of SiO_2 precursors for Si such as SiCl_4 and for the oxidant, O_2 or H_2O could be selected. For some precursor combinations, the mixing process can occur at the entrance to the growth chamber. This may be necessary if there is a reaction between the precursors at ambient temperature.

The reaction chambers can take many different forms, depending on the application but in general can be classified as horizontal or vertical depending on how the gas stream impinges on the substrate. The reaction chamber pressure is typically in the range of 10^{-3} – 10^{-5} Pa. Schematics of vertical and horizontal reactor configurations are shown in Fig. 7. The heated substrate is kept at a temperature significantly higher than the impinging gas or the chamber walls. The chamber walls can be water cooled or just radiate to the surroundings. A pyrolysis reaction will occur between the precursors at or just above the substrate surface. CVD can be used for volume production as a continuous process using a vertical injection of the precursors onto a moving substrate as illustrated in Fig. 7C. This type of configuration is described, by Yates et al. (2012), for deposition of fluorine doped tin oxide for transparent conductors used in thin film photovoltaic production.

Examples of the CVD reactions are given as follows.

These reactions deposit a film onto the heated substrate that must be at a high enough temperature for pyrolysis to occur. With very reactive combinations of precursors such as SiH_4 and O_2 this can considerably suppress the pyrolysis temperature. Volatile reaction products and unreacted precursors are carried out of the reactor in the gas stream and are taken through wet or dry effluent treatment to avoid toxic gases from entering the environment. A recent review of CVD methods is given by Sun et al. (2021) where further details can be found of CVD reactor types, operating conditions and applications.

Fig. 7 Schematics of commonly used CVD reactor configurations, (A) vertical reactor, (B) horizontal reactor, (C) in-line CVD coating.

Graphene CVD and other 2D materials

One of the most common methods for producing graphene 2D films is by a CVD process. The process is catalytic onto a metal surface such as copper. Copper is a good choice as the solubility of copper in graphene is low so has minimal effect on the film properties (Munoz and Gomez-Aleixandre (2013)) it also is self-limiting at one monolayer. Nickel promotes a different kinetic process that can lead to multiple graphene layers. The catalytic process starts with the dissociation of hydrogen to produce hydrogen radicals, which react with the hydrocarbon. The precursors are typically methane in hydrogen but any simple alkane can be used and more complex organics (Saeed et al., 2020). The application of CVD has been extended to the rapidly growing topic of 2D transition metal dichalcogenides such as MoS₂ and WS₂. The precursors are typically chlorides for the transition metal source and hydrides for S (Tang et al., 2020).

Metal organic vapor phase epitaxy (MOVPE)

Metal Organic Vapor Phase Epitaxy (MOVPE) can be viewed as a sub-set of CVD but one that has become pre-eminent in producing high quality epitaxial films of compound semiconductors for applications such as solid state lasers, detectors, high frequency devices and white light LEDs (Irvine and Capper, 2019). A more general term covering epitaxial and polycrystalline thin films is Metal Organic Chemical Vapor Deposition (MOCVD). This was the preferred description by the inventor of this process Hal Manasevit (Manasevit, 1981) and includes polycrystalline thin films in addition to epitaxial films. This differs from CVD in the use of metal-organic precursors for the metal component. For example, GaAs can be deposited from trimethyl gallium (TMG) and arsine (AsH₃). All organometallic sources have also been used for compounds where hydrides are not suitable or to create different kinetic conditions such as for the compounds CdTe (Kartopu and Irvine, 2019) and GaSb (Aardvark et al., 1997). The reactions between the precursors occur within the gas phase boundary layer or at the surface and is a pyrolysis reaction. Some examples of reactions in MOVPE to yield compound semiconductor epitaxial films are given here.

Ternary and quaternary alloys can be grown by adding the appropriate precursors to the gas stream. In the case of all organometallic precursor sources some addition of hydrogen is normally required to produce the stable alkane leaving groups. This would normally be provided with a hydrogen carrier stream. The carrier gas for nitrides is nitrogen. Argon can also be used as an inert carrier gas which can be useful for oxides such as the wide bandgap semiconductor Ga₂O₃, (Zhou et al., 2019).

The reactors for MOVPE are similar to those for CVD and for production scale will be capable of growing uniformly over multiple wafers. There are two main types of MOVPE reactor chamber, horizontal and vertical (Lundin and Talalaev, 2019). Horizontal reactors direct flow horizontally across the substrate and vertical reactors direct the flow normal to the surface of the substrate. In both cases a boundary layer of flow is formed close to the substrate surface and for multi-wafer reactors some form of substrate rotation is used to ensure good uniformity. A picture of the Aixtron AIX 2800G4 15 × 4 inch horizontal planetary reactor is shown in Fig. 8. The organometallic precursors are contained in electropolished stainless steel bubblers and are required to be of

Fig. 8 An example of a production MOVPE reactor chamber. This is the AIX 2800G4 reactor chamber in the 8 × 6 inch configuration for growth of III-V compound semiconductors. Courtesy of Vincent Meric, Aixtron GMBH.

very high purity for epitaxial growth. The carrier gas, which also must be very high purity and low moisture level, is bubbled through the precursor to entrain a saturated vapor of the precursor. Further mixing and dilution with other precursors and the carrier gas will occur prior to introduction into the reactor chamber.

Atomic layer deposition

Atomic layer deposition (ALD) is also referred to as Atomic Layer Epitaxy (ALE) for the epitaxial process and is a variant of the CVD process. The distinct difference between ALD and CVD is in the sequence for feeding the precursors into the reaction chamber. For CVD the precursors are mixed before they reach the substrate but for ALD they are kept separate so the surface is seeing only one precursor at a time. Each precursor saturates the surface in turn and reacts to yield an atomic layer. The sequence for ALD is as follows.

1. The first reactant (A) is introduced into the reactor and saturates the surface.
2. The excess of reactant A and its gaseous products are purged or pumped from the reactor.
3. The second reactant (B) is introduced into the reactor and saturates the surface.
4. The excess of reactant B and gaseous products are purged or pumped from the reactor.

An advantage of ALD over more conventional CVD methods is the ability for conformal coverage over non-planar surfaces (Cremers et al., 2019) with applications in micro-electronics and in nanotechnology. For example, the oxide Al_2O_3 can be used as a passivating layer in semiconducting devices and can be grown with excellent conformal coverage over complex surfaces with the thickness of a few nanometers. Al_2O_3 can be grown by ALD from the precursors trimethylaluminium (TMA) and water vapor (Arts et al., 2019).

Energy-assisted chemical vapor deposition

The CVD processes discussed so far have relied on pyrolysis driven reactions to deposit a thin film. Depending on the material being deposited and the precursors used this can sometimes require a surface temperature of over 1000 °C. Lower temperature deposition can often be achieved by using less stable precursors but this is not always the case. The term energy-assisted" is used generically when additional, non-thermal energy, is used to promote the reaction process at a lower temperature than could be achieved by pyrolysis.

Plasma-assisted CVD

Plasma-assisted CVD can be used to produce materials that are difficult to produce by conventional CVD or where low temperature deposition is required (<400 °C). An example is the plasma-assisted CVD of diamond for high power electronics, requiring very high purity, low defect concentration and a fast growth rate (Silva et al., 2009). These conditions are satisfied by microwave plasma assisted deposition that can supply a high rate of hydrogen radicals to drive the process. The process gasses are hydrogen and methane. Both H radicals and CH_3 radicals are produced by electron bombardment from the plasma. CH_3 attaches to the diamond surface and the H radicals will strip off the H ligands on the surface to leave vacant surface sites for more CH_3 radicals to adsorb. Different kinetic processes occur at different chamber pressures. At low pressure the process is dominated by electron bombardment. At high pressure it is dominated by H radical collisions with CH_4 to yield CH_3 plus H_2 . In either case the key to a successful diamond growing process is the high generation rate of H radicals. More recent developments have enabled plasma assisted CVD of 2D materials such as graphene, MoS_2 and WS_2 (Han et al., 2018).

UV-assisted and photo-assisted CVD

UV-assisted or UV photo-assisted CVD has its origins in the 1980s with a drive to produce high quality semiconductor materials at low temperatures. This was particularly important for II-VI semiconductors where it was necessary to grow at low temperature for a CVD or MOCVD process in order to reduce concentrations of point defects. In a review by Irvine (1987) a number of examples are given of growth temperatures below the pyrolysis temperature for the precursors used. The process of UV-assisted CVD relies on organometallic precursors having strong absorption bands in the UV (<300 nm). These absorption bands result in photolysis of the organic ligands from the metal atom, resulting in deposition of the metal species. The same was also true of the chalcogenide component in the II-VI compound. A disadvantage of UV-assisted CVD is the need for high quality quartz windows that must be kept free of deposit. Longer wavelength stimulation has proved to be easier to manage where surface reactions are stimulated by either a laser or halogen lamp source. This also includes categories of photo-assisted catalytic growth where the photon absorption in the growing film releases charge back to the surface to assist the release of organic ligands. Surface irradiation with a broad band lamp source can stimulate both photo-catalytic and surface pyrolysis type reactions. An example of Photo-assisted MOCVD (PA MOCVD) is using a tungsten-halogen lamp inside the reaction chamber and illuminating the substrate surface. An example of PA MOCVD is given by Li et al. (2008) for the growth of ZnO .

Film growth by condensed-phase reaction

Sol-gel deposition

Sol-gel is a thin film growth technique using a solution of the precursors to deposit, for example, thin films of oxides. It is a low-cost method that can produce high quality polycrystalline films with controlled nanoparticle size. The sol-gel method is multi-step, shown schematically in Fig. 9, as follows (Parashar et al., 2020).

1. Hydrolysis of the precursor in water or alcohols for the synthesis of metal-oxide nanoparticles.
2. Condensation of adjacent molecules to form polymeric networks leading to a colloid. This is the gel phase.
3. Aging process. Changes the structure of the gel to reduce porosity.
4. Drying process. This can take one of three different forms, supercritical drying, thermal drying and freeze drying. Each of these methods will affect the pore density.
5. Thermal treatment/calcination to drive off the residues and water molecules to leave a nanoparticle metal oxide film.

The sol-gel method is finding a diverse range of applications with recent research in antibacterial polymer coatings and marine antifouling coatings (Lelo et al., 2022). Inorganic coatings such as ZnO have applications as optical coatings and in semiconductor devices (Arya et al., 2021).

Chemical bath deposition (CBD)

Chemical Bath Deposition is a solution method commonly used for oxide and chalcogenide thin films (Hone and Abza, 2019) and has advantages of being low cost and deposition low temperature. Ionic salts are dissolved in an aqueous solution to achieve a supersaturation to drive precipitation and film nucleation on a suitable substrate. The solubility of the ionic salts can be adjusted by changing the composition of the solvent using, for example, an alcohol. A complexing agent is used as a catalyst to avoid spontaneous precipitation. This controls the release of the ions into solution affecting deposition rate, film roughness and adhesion. Examples of complexing agents are hydrazine and ammonia. The pH of the solution will control the OH^- ion content which in turn will affect porosity and morphology of the film.

Langmuir-Blodgett deposition

This method entails the transfer of a floating monolayer on the surface of a water bath onto a substrate, slowly withdrawn from the surface. A schematic of the Langmuir-Blodgett method is shown in Fig. 10. The organic molecules need a hydrophilic head group and a hydrophobic tail. The hydrophobic head will bond to the water surface but not dissolve due to the hydrophobic tail. The molecules will spread across the surface but to make a continuous film it is necessary to form a dense packing of the molecules. Isotherms of the surface pressure (π) and the surface area can be plotted to determine the required surface pressure for a dense film. In practice this is achieved using a boom to compress the surface, as shown in Fig. 9. Multiple monolayers can be formed by repeating the passage of the substrate through the surface film. Further details of the Langmuir-Blodgett method and its applications can be found in the review by Rocha Rodrigues et al. (2020).

Electrodeposition

This method relies on an electric current being passed through an ionic solution between an anode and cathode where the cathode is the surface to be deposited. In the example of Cu plating, the anode is made of copper and as the electric current is passed through the $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ electrolyte, Cu^+ cations dissolved from the anode and passes to the cathode, plating it with a copper film. The rate of film deposition is simply controlled by the current and film thickness by the total charge transfer. The process is readily scaled for industrial scale coating, normally of metal films such as electrogalvanizing to deposit a protective zinc film. Anodizing is another electrodeposition technique used to protect metal surfaces such as aluminium. In anodization the part to be coated forms the anode where oxygen ions react with the aluminium surface to form a stable film of Al_2O_3 .

Semiconductor compounds such as CdTe can also be grown by electrodeposition and is particularly attractive for large area coatings for photovoltaic applications (Dharmadasa and Haigh, 2006). The cell potential needs to be carefully controlled to enable simultaneous deposition of both components. A review of deposition conditions and reaction mechanisms is given by Manivannan and Noyel Victoria (2018).

Fig. 9 Schematic of the steps in a sol-gel process.

It is also possible to deposit films by electroless deposition where an electric current is not necessary. In this process, the ion concentration in the electrolyte needs to be sufficiently high to allow deposition. Electroless deposition has an advantage over electrodeposition in that it does not require a conducting substrate. This has made it popular in the electronics industry for depositing Cu conducting tracks and has also proved to be very effective for conformal coverage over non-planar surfaces (Ghosh, 2019).

Liquid phase epitaxy

Liquid Phase Epitaxy is an established technique for producing very high purity epitaxial films of compound semiconductors such as GaAs, AlGaAs, InP and GaP (Kuphal, 1991). Various techniques have been deployed to bring the melt into contact with a substrate but the most versatile is the sliding boat technique, which is illustrated in Fig. 10. This technique has the advantage of allowing multiple layers to be grown to produce detector and laser device structures. The melt composition and temperature must be carefully controlled to create supersaturation for growth. If the substrate is too hot then melt back can occur. This can sometimes be used intentionally to create a clean surface. The growth temperature is typically well below the congruent melting point of the epitaxial layer. A melt is maintained by using a metal solvent such as Ga in the case of GaAs. The composition must be controlled to give growth at the desired temperature following an initial homogenization step at a slightly higher temperature. A small decrease in temperature creates the supersaturation condition for epitaxial growth to occur. Once growth is commenced, a compositional gradient will be established in the melt which will control the growth rate (Fig. 11).

Fig. 11 Schematic of sliding boat LPE.

Conclusion

This chapter has covered a broad range of the most commonly used thin film deposition methods and examples of the range of materials deposited. The precursor for deposition can be either from the vapor or from a liquid. The first section of this chapter has concentrated on the vapor deposition methods from simple evaporation through to chemical vapor deposition. An attempt has been made to draw out common themes such as the gas vapor pressure and mean free path. These factors determine the degree of interaction between the gas phase molecules that dictate the degree of pre-reaction and transport mechanism to the growth interface. The choice of method depends on factors such as the volatility of the elements to be deposited, deposition temperature and application. Many of the vapor phase deposition methods have reached large scale industrial production for a range of applications including ion assisted deposition for high temperature and hard coatings, sputter deposition for a wide range of optoelectronic and electronic functional coatings, CVD for coating of glass and MOCVD for compound semiconductor devices.

Future directions in coating technology for protective coatings will face the challenge of higher temperature operation and more aggressive environments. For example, ceramic matrix composites for gas turbine engines operating at gas inlet temperatures of $>1700^\circ\text{C}$. At the other end of the scale, environmental barrier coatings for the marine environment will be required for anti-fouling without causing pollution. Sol-gel has proved to be a versatile and easily scalable process that could provide the means for large-scale protective coatings.

The rapid growth in electronic and opto-electronic devices from computer chips to infrared lasers for fiber-optic communications has heavily depended on developments in thin film coatings. Production scale MOCVD has driven the revolution in high efficiency lighting based on GaN LEDs. Future prospects are for new materials such as gallium oxide and 2D transition metal dichalcogenides to provide a new generation of electronic devices. Graphene produced by CVD is another rapidly growing application where integration with silicon could revolutionize computer chips.

Another rapidly growing industry is photovoltaics (PV) for solar energy conversion. The industry is currently dominated by silicon but still depends on thin film coating for surface passivation and conductors. Second generation thin film PV is now reaching large scale production with Cadmium telluride and copper indium gallium diselenide (CIGS). Large scale thin film deposition uses physical vapor deposition. Future prospects exist for the perovskite solar cells with MAPI (methyl ammonium lead iodide) being the most successful to date but with a wide range of alternative compositions that can be explored to achieve high efficiency, low-cost materials supply and good environmental compatibility. The materials can be deposited by CVD methods or by solution based methods where, in the latter case, the films can be printed onto a suitable substrate such as glass or sheet steel in a continuous process.

Future development of thin film growth, whether they be solution or gas phase deposition will be driven by demands for new materials for higher performance, durability and at lower cost. The latter will depend on market prices for materials where lower cost alternatives with the same or better performance might be achieved. The cost of thin films will also be driven by the efficiency of utilization of the precursor materials. This becomes an increasing concern as the processes go to larger scale. The design of an RF sputtering system to achieve high utilization of the targets or for CVD a high reaction rate to minimize the amount of unreacted precursor passing to the exhaust effluent treatment. Finally, I would like to mention conformal coverage of coatings. For protective coatings the existence of pin-holes will be a point of failure but the surface being coated could be microscopically rough. For electronic devices there is a demand for thinner coatings that nevertheless have to be conformal. For example, a thin dielectric layer could produce shunt paths if the coating is not continuous. For example, ALD has proved to be a technique with exceptional surface coverage for very thin films. The ultimate challenge will be conformal coverage of monolayer 2D materials that will stretch the limits of thin film deposition technology.

Introduction

Materials in the form of thin films (layers having thicknesses of a few micrometers or less) are the basic building blocks of microfabricated or nanofabricated devices such as integrated microelectronic circuits. They are used as electrical conductors and insulators, magnetic layers, optical reflectors and absorbers, chemical passivations and catalysts, and as structural elements. Although often intended for nonmechanical functions, the mechanical properties of thin films are very important. Thin films are typically found attached to much more massive substrates, and the constraint of the substrate can lead to very high stresses in the film. These stresses may, in turn, lead to failure by a variety of mechanisms, including excessive elastic or plastic deformation, void formation, fracture, or delamination. Understanding the stress states in, and the mechanical response of, thin films is thus a prerequisite to optimizing reliability in microfabricated and nanofabricated devices.

Achieving this goal is complicated by the fact that the mechanical behavior of thin films often does not follow the scaling laws developed for bulk materials. Thus, the mechanical properties of thin films must be measured directly. In this article, the sources of stress in thin films, common mechanical property measurements, and some factors that determine non-bulk-like mechanical response in thin films are briefly reviewed.

Thin Film Stresses

While thin films may experience stresses due to externally applied loads, the largest source of stress in a film typically arises from an interaction between the film and substrate. The origins of these stresses can be understood by the simple thought experiment shown in Figure 1. In Figure 1a, a stress-free film is shown attached to a substrate. Because the film is stress free, one can imagine that it is removed from its substrate without changing dimensions as shown in Figure 1b. One can then imagine that some process occurs that changes the in-plane dimensions of the film relative to the substrate. For example, suppose the film shrinks relative to the substrate as shown in Figure 1c. Since there is no interaction between the film and the substrate, each attains its equilibrium dimension and remains stress free. The film can then be returned to the substrate by imposing a biaxial stress on the detached film in order to elastically deform it, until it again has the same dimension as the substrate, as shown in Figure 1d, and reattaching the film to the substrate, as shown in Figure 1e. To complete the thought experiment, the externally applied forces are removed. The final configuration is shown in Figure 1f. The film continues to support biaxial stresses, and the substrate distorts elastically due to the forces transmitted across the film/substrate interface.

Any process that changes the equilibrium dimensions of the film and the substrate, relative to each other after the film has been deposited on the substrate, will lead to substrate interaction stresses. These dimensional changes can arise from four different sources: (1) Thermal strains arise due to differential thermal expansion. If the elastic strain in the film is zero at some temperature, T_0 , then the elastic strain required in the film to accommodate the thermal strains at any other temperature, T , is

$$\epsilon_{\text{th}} = \int_{T_0}^T (\alpha_s(T) - \alpha_f(T)) dT \quad [1]$$

Figure 1 Thought experiment showing how an interaction between a film and substrate leads to high stresses in the film (description in text). Any process that changes the equilibrium in-plane dimension of the film relative to the substrate after the film is attached to the substrate leads to high stresses in the film.

where $\alpha_f(T)$ and $\alpha_s(T)$ are the (temperature dependent) thermal expansion coefficients of the film and substrate, respectively. (2) Structure evolution strains arise from structural changes that change the density of the film. Grain growth, densification, ion implantation, chemical reactions, and phase changes are common sources. The accommodation strain in such cases is given by

$$\varepsilon_{\text{evol}} = \frac{-e_T}{3} \quad [2]$$

where e_T is the dilatational strain associated with the structure evolution. (3) Epitaxial strains arise when the film is deposited in such a way that there is some crystallographic registry between the film and substrate. If the pertinent in-plane lattice parameters, a_s and a_f , of the film and substrate, respectively, are not the same, then the elastic strain required in the film is

$$\varepsilon_{\text{epi}} = \frac{a_s - a_f}{a_f} \quad [3]$$

(4) Surface (interface) stresses arise from the change in bonding at free surfaces and interfaces compared to that in the bulk. While the forces arising from a single interface are small, surface stresses can be significant in multilayer films where the interface density is high. For a multilayer consisting of alternating layers of materials A and B having thicknesses t_A and t_B , respectively, the total stress exerted on the substrate is

$$\sigma_{\text{int}} = \frac{2(f_{A/B} + f_{B/A})}{t_A + t_B} \quad [4]$$

where $f_{A/B}$ is the interface force per unit width of A at an A/B interface, and $f_{B/A}$ is the interface force per unit width of B at a B/A interface.

Substrate interaction stresses, particularly those arising from structure evolution strains, are often referred to as “intrinsic,” but this terminology should be avoided since the stresses are not intrinsic to either the film or the substrate but rather always arise from an interaction between the two. Because the structure in films can be inhomogeneous, the stresses in films can be inhomogeneous as well.

Measurements of Thin Film Deformation

Measuring mechanical properties in thin films is challenging because of the difficulty in manipulating such a thin object. This problem has been overcome by testing films while they are still attached to their substrates or by using microfabrication or nanofabrication methods to prepare samples without the need to handle the film.

The most common tests are nanoindentation and substrate curvature methods, in which the film is tested while still supported by the substrate. Commercial equipment is available for both of these tests. In nanoindentation, the load and displacement are recorded as a hard tip of a known shape is pressed into the sample surface and removed. By the use of an appropriate analysis model, a measure of elastic stiffness, hardness, and time-dependent behavior can be obtained. Nanoindentation tests are simple to perform, and quantitative information can be obtained from very small (tens of nanometers in diameter), well-located (within some tens of nanometers) volumes of materials. However, the primary disadvantage of nanoindentation lies in distinguishing film properties from substrate influences, which arise as indentations become large and surface influences (mainly due to roughness, surface layers, or particles), which become large as indentations become small.

Substrate curvature tests make use of the curvature shown in Figure 1f. If the film is thin and/or compliant relative to the substrate, then the stress in the film is related to the curvature induced via

$$\sigma = Y_s \frac{t_s^2}{6t_f} \left(\frac{1}{R} - \frac{1}{R_0} \right) \quad [5]$$

where R_0 and R are the radii of curvature of the substrate before and after the film is attached, respectively, t_f and t_s are the thicknesses of the film and substrate, respectively, and $Y_s = E_s/(1 - \nu_s^2)$ is the biaxial modulus of the substrate, assumed to be isotropic with Young's modulus, E_s , and Poisson's ratio, ν_s . Equation [5] is known as the Stoney equation and applies when the product of ratios $t_s Y_s / t_f$ is large, typically greater than ~ 100 . R_0 and R are typically measured either by scanning a laser across the sample and observing the position of the reflected beam, or using optical interferometry. The substrate curvature method is very accurate and repeatable, as well as relatively simple and flexible. It is often used *in situ* to measure the stresses that arise in films during deposition or thermal cycling. The main disadvantage is that it is not possible to control the strain without changing the conditions that give rise to that strain (e.g., change in temperature).

Results from substrate curvature measurements conducted *in situ* during thermal cycling of 1 μm thick Cu films are shown in Figure 2, and provide an introduction to several unique features of thin film deformation behavior. Such tests are often used because they mimic the thermal cycles that films undergo during manufacture and use. Three sets of data are shown. The solid line indicates data obtained from a computer simulation based on steady-state deformation mechanisms for bulk Cu, including the microstructural length scales of the film. The open and filled circles are data from substrate curvature measurements. The Cu films were prepared identically except that a thin passivation layer was deposited on one, while the other was left with the Cu-free surface exposed. The shapes of the experimental stress–temperature hystereses in Figure 2 show that the stresses can be much higher in thin films than in comparable bulk materials, particularly at high temperatures.

In recent years, a number of tests have been developed to test free-standing films or parts of films. The two most common examples are bulge tests and microtensile tests. In bulge tests, microfabrication methods are used to remove a section of the substrate from behind a film, and pressure is applied to cause the film to bulge out. With an appropriate analysis model, pressure–deflection data can be converted to stress–strain data. For microtensile tests, free-standing tensile test samples are prepared by first removing the adjacent film material and then removing the substrate from behind the sample, leaving a substrate frame to which the sample remains attached at both ends. Loads are applied to these substrate sections to distort the film. Microfabricated test structures are of great interest for the study of free-standing thin film structures.

Plastic Behavior

As is the case in bulk materials, the plastic behavior of thin films depends on the microstructure. Unlike bulk materials, however, the plastic behavior of thin films is often found to depend on the sample size. In addition, the plastic behavior of thin films is extremely sensitive to conditions at thin film interfaces.

The microstructures of crystalline thin films may be categorized into three groups: Single-crystal films arise primarily when films are deposited epitaxially. Nonepitaxial films are often nanocrystalline (grain sizes $\sim 10\text{ nm}$) in their as-deposited state. The mechanical behavior of such films is similar to that of “bulk” nanocrystalline materials and is not considered here. If a

Figure 2 Stresses induced by thermal cycling in Cu films on Si substrates. The films were prepared identically except that a thin SiNx passivation layer was deposited on one. The solid line is a simulation showing the behavior expected based on scaling laws derived for bulk Cu.

fine-grained film is annealed, the mean final grain size is often found to be of the same order as the film thickness. Such films typically have “columnar” grain structure (all grain boundaries perpendicular to the plane of the film), in which certain orientations are strongly preferred. For example, in f.c.c. metal films, grains with (1 1 1) and (1 0 0) planes parallel to the plane of the film are most common as they minimize interface and strain energy, respectively.

Dislocation Mediated Plasticity

The high strength of crystalline thin films at low temperatures (Figure 2) is due to constraints on dislocation motion. An epitaxial thin film on a substrate provides a simple example of how the constraint of the substrate affects the mechanical behavior of thin films. A film with a capping layer is illustrated in Figure 3. A threading dislocation (a dislocation that runs from the top to the bottom of the film) is shown at “a” of Figure 3 in an unstressed film. When a stress is applied, the threading dislocation can relax the applied strain by moving on its glide plane. However, because the film is encapsulated between the substrate and cap layer, the threading dislocation can only move ahead by leaving misfit dislocations behind at the interfaces (indicated by “b” in Figure 3). The threading dislocation moves forward only when the elastic strain energy relieved by its motion is sufficient to provide the energy required to form the misfit dislocation. Thus, there is a threshold stress (critical stress) for dislocation motion. Since the total strain energy in the film depends linearly on the film thickness and the energy per unit length of the misfit dislocation is approximately constant, the critical stress varies with reciprocal film thickness. A widely used derivation gives

$$\sigma_c = \frac{\sin \phi}{\sin \phi \cos \lambda} \frac{b}{2\pi(1-\nu)t_f} \times \left[\frac{\mu_f \mu_s}{(\mu_f + \mu_s)} \ln \left(\frac{\beta_s t}{b} \right) + \frac{\mu_f \mu_p}{(\mu_f + \mu_p)} \ln \left(\frac{\beta_p t_p}{b} \right) \right] \quad [6]$$

Figure 3 A dislocation gliding on its slip plane in the channel created by a thin film between a substrate and a passivation layer. (a) A threading dislocation extends from the top of the film to the bottom at zero stress. (b) In order to move through the film, the dislocation must leave misfit dislocations at the film/substrate and film/passivation interfaces.

where b is the magnitude of the Burgers vector, φ and λ are the angles between the film normal and the glide plane normal, respectively, μ the shear modulus, and β a constant. The subscripts f, s, and p refer to the substrate, film, and passivation layers, respectively.

The concept of critical strain is particularly important in microelectronic devices containing epitaxial semiconductor layers, as the misfit dislocations that form when the critical strain is exceeded can spoil the electronic function of the device. The reciprocal dependence of critical stress on the film thickness predicted by eqn [6] has been observed in epitaxial semiconductor films. However, higher values have also been reported. This may be due to experimental difficulties associated with observing the formation of the first misfit dislocations, or to a lack of appropriate dislocation sources. From a reliability perspective, eqn [6] provides an accurate measure of the minimum thickness at which misfit dislocations may appear in an epitaxial film.

Interestingly, an inverse dependence of strength on thickness is also seen in polycrystalline metal films, although at stress levels much higher than those predicted by eqn [6]. One can obtain such data, for example, by recording the stress at room temperature at the end of thermal cycles as in Figure 2 for films of various thicknesses. Neither the fact that the yield stress increases as t_f decreases, nor that eqn [6] underpredicts the result, is surprising. As strain increases, a threading dislocation moving through the film must interact with misfit dislocations in its path as well as other threading dislocations and is constrained from long-range motion by grain boundaries, just as in bulk materials. That these events occur in the narrow channel of the film leads to very high stresses indeed. However, while a number of models have been presented, the precise origin of the t_f^{-1} dependence is not yet clear.

The arguments above are based on the assumption that dislocations are preserved at the interfaces. If dislocations are not preserved, then the behavior will be very different. The limiting case is that of a free-standing film, which has no critical strain threshold for dislocation motion and no misfit dislocations to block the threading dislocation motion. A film with one free surface (e.g., Figure 2) represents an intermediate case. However, a free surface is not needed to eliminate misfit dislocations. If the resistance to interface sliding is sufficiently low, then the cores of misfit dislocations can spread into the interface. The consequence is that the mechanical behavior of certain film systems (e.g., copper on nitride or oxide layers, as is commonly used in microelectronics) is very sensitive to any variation in interface chemistry that affects interface strength. Stress levels in fully encapsulated films can be varied over a wide range in this manner.

Another example of interface control of properties is multilayer films, in which manipulation of interface strength and density can be used to create exceptionally strong films. For example, by deposition of alternating thin layers with well-bonded, dislocation blocking interfaces, films with strengths approaching the theoretical strength can be generated.

Diffusion Mediated Plasticity

At high temperatures, the high strength of thin films is due to constraints on diffusion, and the difference between thin film behavior and that expected on the basis of bulk scaling laws is even more dramatic. For example, at the low strain rates imposed for the data in Figure 2, the simulation predicts that the stress would be relaxed to near zero at temperatures above 400°C, while the real films support significant stresses at these temperatures.

This discrepancy can be understood as follows: Figure 4 shows a schematic cross section of a film on the substrate with a capping layer. A stress applied in the plane of the film can be relaxed if the material diffuses between the grain boundaries and the interfaces as shown in Figure 4a. The simulation in Figure 2 was obtained by assuming that the interface diffusivity is the same as the grain boundary diffusivity. In order to achieve the stresses seen in the real capped film at high temperatures, interface diffusion must be turned completely off in the simulation and relaxation allowed to occur by other mechanisms, such as thermally activated dislocation glide. While high stresses due to limited interface diffusivity might be expected in tightly bound interfaces such as Al/SiO₂, similar high stresses are often seen in films with interfaces known to have poor adhesion and high diffusivity such as Cu/SiN_x. The reasons for this are presently unknown.

An uncapped film provides an interesting case, as shown in Figure 4b. Here diffusion is allowed between the grain boundaries and the free surface, but not between the grain boundaries and the interface with the substrate. Tensile stresses, for example, are relaxed by diffusion of material from the free surface into the grain boundaries. Each grain boundary is filled with a wedge of material and the stresses are relaxed near the film surface, but not near the interface. This provides an inhomogeneous stress state with high shear stresses on the interface.

Elastic and Anelastic Behavior

Elastic strain is deformation that is fully recovered upon removal of the applied load. This definition encompasses both elastic deformation that arises from bond stretching and twisting, and anelastic deformation that arises from atomic reconfigurations (e.g., defect motions). Elastic deformation occurs at short timescales (transmitted at phonon velocities) while anelastic deformation is time dependent on a much longer scale.

Elastic deformation depends on the type and density of interatomic bonds in the material. One does not expect radically new types of interatomic bonds in a film just because it is thin. Indeed, the changes that can be expected in elastic constants should be of the order of $N_{\text{defect}}/N_{\text{bulk}}$, the ratio of atoms in nonbulk environments to the number in bulk environments. For example, consider a film comprised of cubic grains with side d having boundaries of width δ . The ratio of grain boundary to interior volume is $3\delta/d$.

Figure 4 (a) Stresses can be relaxed in a passivated film only if diffusion is allowed along the interfaces. (b) In an unpassivated film, stresses can be relaxed by diffusion between the grain boundaries and the free surface.

If the grain interiors have modulus E_{grain} and the boundaries have a modulus of zero (an extreme example!), then the isostrain composite modulus of the film is

$$E = (1 - 3\delta/d)E_{\text{grain}} \quad [7]$$

For $\delta=0.2$ nm, one would need $d=6$ nm ($=t_f$) to achieve a modulus reduction of only 10%. Given this expectation, a great deal of excitement has accompanied reports of much larger deviations. However, it now appears that all such reports can be attributed to experimental errors.

Anelastic behavior, on the other hand, can be much more prominent in thin films than in bulk. An example can be seen in Figure 2. Upon initial heating, the experimental data initially follow the predicted thermoelastic slope. At some point, the data deviate from this slope, indicating the onset of inelastic deformation. Careful inspection reveals that the inelastic strain is compressive, while the applied stress is still tensile. This “negative yielding” is similar to the well-known Bauschinger effect in bulk metals, but is much larger. As is the case with plastic deformation by both dislocation and diffusion mediated plasticity, anelastic recovery is also very sensitive to interface conditions. For example, quite spectacular anelastic recoveries of up to several tenths of a percent strain can be achieved by adjusting interface adhesion.

Two mechanisms, dislocation motion and boundary sliding, that are often used to explain anelastic behavior in bulk metals, probably also account for anelastic behavior in films. For example, consider a film that has been plastically deformed so that loops having the form shown in Figure 3 have been generated at stress levels above σ_{ch} (eqn [6]). If the applied stress is then reduced below σ_{ch} , it becomes energetically favorable for the dislocation loops to run out of the film, increasing the strain energy (and stress) in the film, but reducing the total energy by reducing misfit dislocation line length. The quasi-2D structure of films can promote grain boundary sliding by allowing grain rotations in the plane of the film. In addition, shear stresses along the film/substrate interface generated by anisotropy or diffusional mechanisms can be relaxed by sliding along the interface, which can also lead to anelastic behavior.

The highly textured nature of films also leads to non-bulk-like scaling behavior. For example, a film composed of a cubic material has lower stiffness, but higher surface energy when (1 0 0) planes are parallel to the plane of the film compared to the case where (1 1 1) planes are parallel to the film plane. Thus, a transition from (1 1 1) to (1 0 0) orientation (stiff to compliant) with film thickness has been predicted and experimentally verified. For Cu, Ag, and Au, for example, the difference is more than a factor 2. For a given elastic strain, the stresses are then much higher in the (1 1 1) orientations, leading to very inhomogeneous stress states and high shear stresses on the interfaces near (1 1 1)/(1 0 0) grain boundaries.

Fracture and Delamination

Brittle films with sufficiently weak interfaces may fail by delamination from the substrate (Figure 5a) or by fracture (Figure 5b). The driving force, G , for delamination can be found by comparing the elastic strain energy per unit area of the film far ahead of the delamination crack with that which is far behind the crack. For a straight crack front,

Figure 5 (a) Delamination of, and (b) through thickness (channeling) cracks in a thin film.

$$G = \frac{1 - \nu_f^2}{2E_f} \sigma^2 t_f \quad [8]$$

where σ is the stress in the film before delamination.

Several tests have been developed for quantitative assessment of the interfacial fracture toughness, Γ , or the value of G at delamination. If the stress in the film is well known, the thickness at which it delaminates can be used to determine Γ from eqn [8]. In many cases, a highly stressed “superlayer” is added on top of the target film of interest to accelerate the process. While the solution is more complicated, it is straightforward to find Γ for the target interface if the stresses in the layers and their thicknesses are known. In addition, several tests of film adhesion have been developed, which do not require a detailed knowledge of film stress states. In these tests, the film is bonded between two massive substrates and external loads are applied to the substrates to drive a delamination crack. These tests include the four-point bend test, the double-cantilever beam test, and several others.

Because thin films are normally under stress, subcritical delamination is an important failure mode and topic of study. Subcritical delamination occurs when chemical processes assist crack propagation so that films delaminate under conditions where G is less than the value required for rapid or “critical” crack propagation in the absence of chemical assistance. Under constant stress, subcritical delamination may occur very slowly over very long durations and is a particularly insidious failure mode. Recent work suggests that subcritical delamination of thin films is similar to subcritical cracking in glass with a region where crack velocity v depends exponentially on G when the chemical reaction rate is controlling, and a region at higher G where v is independent of G when diffusion of the chemical species to the crack tip is controlling.

Cracks that extend through the film thickness (Figure 5b), also known as channeling cracks, are similar to channeling dislocations (Figure 3) in that there is a critical stress needed for channeling crack propagation, established by the requirement that the strain energy released by the crack propagation must be sufficient to produce the new surface area and other energy costs associated with the crack. Channeling cracks, such as channeling dislocations, can also form arrays to relax strains and form configurations that depend on both interactions and sources. The mechanics of film cracking are well developed.

Conclusion

Films on substrates normally support very high stresses due to the constraint of the substrate, but do not exhibit the mechanical behavior of chemically equivalent bulk materials, and thus must be separately studied. While a number of dislocation- and diffusion-based mechanistic models for film deformation have been proposed, a complete model capable of predicting the plastic and anelastic behavior of a film based on its microstructure remains elusive. A significant factor in this is that the microstructural configurations that are assumed in such models have not been sufficiently well verified experimentally. In general, thin films follow

the rule that “smaller is stronger.” This is an area of ongoing development, and new experimental methods and models are expected to extend a detailed knowledge to smaller length scales and both shorter and longer timescales.

Abstract

This article provides a review of methods and results concerning the electronic and transport properties of aperiodic solids.

Key points

- Aperiodic materials, examples
- Conductivity properties of aperiodic materials
- Delone sets and construction of the hull, examples from quasicrystals
- Observable algebra, how to deal with lack of periodicity, the Brillouin zone as a noncommutative manifold
- The integrated density of states, local density of states, Green–Kubo formula for conductivity, numerical calculations and examples
- Characteristic exponents for the density of states, the local density of states, the transport exponents, Guarneri’s inequalities
- Qualitative behavior of the conductivity, the anomalous Drude formula

Aperiodic media

Several classes of aperiodic solids have been the focus of attention in Material Sciences, Condensed Matter Physics, from the point of view of experiments or theory. Examples of such materials are the following:

1. Electrons in a uniform magnetic field are sensitive to the vector potential, which cannot be constant in space at non vanishing magnetic field, thus breaking the translation symmetry (Landau, 1930; Peierls, 1933; Shoenberg, 1984).
2. Randomly distributed impurities or defects break the translation invariance in crystal-like normal metals or doped semiconductors (Anderson, 1958; Shklovskii and Efros, 1984; Akkermans et al., 1995). However, electrons feel them only at low temperature. Similarly only phonons of short wavelength are sensitive to disorder.
3. Amorphous materials, such as glass, silicon (in its amorphous phase) (DiVincenzo et al., 1984), and even liquid at short time scale, have been considered in the literature (Bernal, 1964; Johnson, 1999; Inoue, 2000; Langer J, 2006).
4. Artificial structures, like *superlattices* or arrays of quantum dots, are technologically available and can be designed to break the translation symmetry.
5. Quasicrystals, such as $\text{Al}_{62.5}\text{Cu}_{25}\text{Fe}_{12.5}$ or $\text{Al}_{70.5}\text{Pd}_{22}\text{Mn}_{7.5}$, have a point-like diffraction spectrum with symmetries (like the 5-fold or 10-fold symmetries) incompatible with spatial periodicity (Shechtman et al., 1984; Hippert and Gratias, 1994; Kremer, 1996).

In view of the growing importance of aperiodic materials, there is a need for mathematical and numerical methods to study them, since the usual Bloch theory (Jones, 1975; Ashcroft and Mermin, 1976) cannot be used, due to the lack of translation symmetry. To avoid complexity, as a first approximation, the degrees of freedom (electrons, holes, phonons, and lacunae) will be considered as independent and moving in an infinite volume limit ideal solid.

Transport mechanisms

Various mechanisms of electronic transport can be observed experimentally in aperiodic materials.

- (i) For metals, the conductivity increases as the temperature decreases. Moreover, the Fermi liquid theory (Landau) predicts (Pines and Nozières, 2018; Mahan, 2000)

$$\sigma(T) \stackrel{T \downarrow 0}{\sim} T^{-2}.$$

- (ii) Thermally activated processes (if a gap arises at the Fermi level), give (Ashcroft and Mermin, 1976)

$$\sigma(T) \stackrel{T \downarrow 0}{\sim} e^{-\Delta/T}.$$

- (iii) For weakly disordered systems (strongly doped semiconductors and normal metals), there is a residual conductivity at low temperature, due to *quantum interferences* (Bergmann, 1984)

$$\sigma(T) \stackrel{T \downarrow 0}{\sim} \sigma_0 > 0.$$

- (iv) In strongly disordered systems (lightly doped semiconductors) with small density of states (DOS) at the Fermi level, *Mott variable range hopping* predicts in dimension d (Mott, 1968; Shklovskii and Efros, 1984)

$$\sigma(T) \stackrel{T \downarrow 0}{\sim} e^{-(T_0/T)^{1/(d+1)}}.$$

- (v) High-quality quasicrystals are metallic alloys but their conductivity decreases with the temperature (see Fig. 1) and exhibits a scaling behavior (Berger et al., 1991; Berger, 1994)

$$\sigma(T) \stackrel{T \downarrow 0}{\sim} \sigma_0 + aT^\gamma, \quad 1 < \gamma < 1.5$$

on a large range of temperatures (from 50 mK to 1000 K in some cases). In most cases, $\sigma_0 > 0$ (residual conductivity) but there are examples for which $\sigma_0 \approx 0$ (cf. Fig. 1).

The Hull

The *Hull* of an aperiodic solid and its canonical transversal (Bellissard, 1986), or *atomic surface*, is the main construction (as the Brillouin zone for a crystal). It represents in a compactified way all possible samples of the material that can be ideally produced.

As a good approximation, atomic nuclei are supposed to be frozen at their ideal equilibrium position at zero temperature. The set $\mathcal{L}$ of atomic positions is thus a discrete subset of the space $\mathbb{R}^d$ (d is the dimension of the material). $\mathcal{L}$ is called *uniformly discrete* whenever the minimum distance between any two distinct points of $\mathcal{L}$ is positive. $\mathcal{L}$ is called *relatively dense* whenever there is a radius R large enough so that any ball of radius R meets $\mathcal{L}$ on at least one point. A set is *Delone* if it is both uniformly discrete and relatively dense. A Delone set is *repetitive* if, given any finite patch p (namely a finite set of the form $p = \mathcal{L} \cap B$ where B is some open ball), and any small length $\varepsilon > 0$, there is a radius $R_p > 0$ such that any ball of radius R_p contains a translated copy of p modulo an error smaller than ε . A Delone set has *finite type* if the set of vectors joining two of its points is itself discrete (this latter set is denoted by $\mathcal{L} - \mathcal{L}$). At last, a *Meyer set* is a Delone set such that the family $\mathcal{L} - \mathcal{L}$ of vectors joining two of its points is itself a Delone set (Lagarias, 1996, 1999; Lagarias and Pleasants, 2003).

Fig. 1 Conductivity of two examples of quasicrystals.

Examples:

- (i) Throwing point randomly in space with fixed density (Poisson's law) gives a discrete set which, with probability one, is neither uniformly discrete nor relatively dense.
- (ii) Throwing randomly impurities on sites of a silicon perfect diamond lattice gives a uniformly discrete which, with probability one, is not relatively dense.
- (iii) In the ideal limit of zero temperature, most solids have their atoms distributed on a Delone set (Bellissard et al., 2010). But amorphous ones, like glass or silicon, have not finite type and are not repetitive because their two-point correlation function falls off quickly at large distance. Perfect crystals and quasicrystals are described by a finite type repetitive Delone set (Lagarias, 1999).
- (iv) Typical examples of Meyer sets are provided by crystals and quasicrystals (see Fig. 2). These are the sets with point-like diffraction pattern and no diffuse part.

The solid is *homogeneous* whenever $\mathcal{L}$ and $\mathcal{L} + a$ have similar global physical properties. However, an observer sees only a finite sample in practice, namely, he sees only what happens in a *bounded window* $\Lambda \subset \mathbb{R}^d$. A sequence $\mathcal{L}_n = \mathcal{L} + a_n$ of translated is said to *converge to* the discrete set $\mathcal{L}_\infty$ if and only if, for any bounded window Λ the family $\mathcal{L}_n \cap \Lambda$ of points of $\mathcal{L}_n$ contained in Λ converges to $\mathcal{L}_\infty \cap \Lambda$. The *Hull* Ω of $\mathcal{L}$ is defined as the family of limit points of translated of $\mathcal{L}$. By construction, any point $\omega \in \Omega$ corresponds to a set $\mathcal{L}_\omega$ obtained as the limit of a subsequence of translated of $\mathcal{L}$. It can be proved that, as soon as $\mathcal{L}$ is uniformly discrete, Ω is a *compact* and *metrizable* set (Bellissard et al., 2000).

- Metrizability means that the topology defined above can be described through a metric. An example of such metric (it is not the only one) is the following: the distance $d(\omega, \omega')$ between the points ω, ω' of the Hull is the smallest number $\varepsilon > 0$ such that $\mathcal{L}_\omega$ and $\mathcal{L}_{\omega'}$ coincide in the ball centered at the origin of radius $1/\varepsilon$ modulo an error of ε .
- Compactness means that the set can be approximated by a finite one. Namely, given any $\varepsilon > 0$, there is a finite set $\{a_1, \dots, a_d\}$ of vectors $\mathbb{R}^d$ such that any ω is within the distance ε of at least one of the $\mathcal{L} + a_i$'s. Hence in a ball of radius $1/\varepsilon$, $\mathcal{L}_\omega$ looks like $\mathcal{L} + a_i$ modulo an error smaller than ε .

In other words compactness of the Hull is a way of expressing that $\mathcal{L}$ describes an homogeneous solid. In particular the minimum distance between distinct points in $\mathcal{L}_\omega$ is at least equal to the one in $\mathcal{L}$. Moreover the properties of being Delone, finite type, repetitive, and Meyer are inherited by all the $\mathcal{L}_\omega$ s.

In addition, if $a \in \mathbb{R}^d$ is a vector in space, then $\mathcal{L}_\omega + a$ also belongs to the Hull, thus defining point denoted by $\tau^a \omega$. It can be shown that the map $(a, \omega) \mapsto \tau^a \omega$ is continuous and satisfies $\tau^{a+a'} \omega = \tau^a(\tau^{a'} \omega)$ while $\tau^0 \omega = \omega$, hence giving a *topological action* of the translation group on the Hull. Therefore $(\Omega, \mathbb{R}^d, \tau)$ is a *topological dynamical system*.

To build the Hull, it is convenient to use the *canonical transversal* also called the *atomic surface* Ξ , defined as the set of points ω in the Hull such that the set $\mathcal{L}_\omega$ contains the origin $0 \in \mathbb{R}^d$ (see Fig. 3). Starting from a point in Ξ and translating it, it takes a minimum distance between two points in $\mathcal{L}$ at least to have $0 \in \mathcal{L}_\omega + a$ again. So $\mathcal{L}_\omega$ can be seen as the trace of Ξ in the *orbit* of ω . Since such an

Fig. 2 A Meyer set: the Ammann–Beenker tiling.

Fig. 3 Schematic view of the atomic surface (canonical transversal).

Fig. 4 The atomic surface (canonical transversal) of the Ammann–Beenker tiling (its topology, inherited from the construction, is discontinuous along any line boarding the colored areas as well as all their translated along the directions of the four vectors $e_i^\perp$, $i = 1, 2, 3, 4$).

orbit can be seen as the space $\mathbb{R}^d$ in which the solid is living and since the points of $\mathcal{L}_\omega$ are the positions of atoms, Ξ represents where the atom is in the Hull. This is why Ξ is also called (especially in quasicrystallography) the *atomic surface*.

For periodic materials, the Hull is the d -torus obtained by identifying points in spaces that differ by a vector of the period group (the Bravais lattice). The transversal is the (finite) set of atoms of the unit cell. For quasicrystals, the Hull is a torus of higher dimension in which the physical space $\mathbb{R}^d$ has irrational slopes. Moreover, the Hull has the topology of a Cantor set in the direction perpendicular to the physical space (see Fig. 4).

Noncommutative Brillouin zone

The description of dynamical degrees of freedom (electrons, holes, and phonons) cannot be done through Bloch theory since the translation invariance is broken. However any observable describing them can be given by a *covariant operator* namely a family $A = (A_\omega)_{\omega \in \Omega}$ of self-adjoint bounded operators acting on the Hilbert space $\mathcal{H}$ of quantum states such that (i) $T(a)A_\omega T(a)^{-1} = A_{T^a\omega}$

if $T(a)$ is the translation operator by $a \in \mathbb{R}^d$ acting on $\mathcal{H}$ and (ii) for any quantum state $|\psi\rangle$ the map $\omega \mapsto A_\omega|\psi\rangle$ is continuous (*strong continuity*). If the material is periodic, all such observables are matrix valued functions over the Brillouin zone. Hence the algebra of observable is the noncommutative analog of the space of continuous functions on Brillouin zone, leading to the notion of *Noncommutative Brillouin Zone* (NCBZ). Such functions can be integrated: if $\mathbb{P}$ is an $\mathbb{R}^d$ invariant probability measure on the Hull, then $\mathcal{T}_{\mathbb{P}}(A)$ is defined as the average of the diagonal matrix elements of A_ω and is equal to the *trace per unit volume* of A . The map $A \mapsto \mathcal{T}_{\mathbb{P}}(A)$ is linear, positive (namely $\mathcal{T}_{\mathbb{P}}(A^*A) \geq 0$), and *tracial* namely $\mathcal{T}_{\mathbb{P}}(AB) = \mathcal{T}_{\mathbb{P}}(BA)$. It is the noncommutative analog of the integral over the NCBZ. In addition, if $\vec{R} = (R_1, \dots, R_d)$ is the *position operator*, then $\vec{\nabla}A = i[\vec{R}, A]$ gives a family of d commuting derivations (namely, $\vec{\nabla} = (\partial_1, \dots, \partial_d)$ is linear and obeys the *Leibniz rule* $\vec{\nabla}(AB) = \vec{\nabla}(A)B + A\vec{\nabla}(B)$ generalizing the derivatives *w.r.t.* the quasimomentum in the NCBZ. Depending upon the degrees of freedom (electrons, holes with spin or spinless, or phonons) this algebra of observable will be represented in various Hilbert spaces. Most formulae found in textbooks, valid for periodic crystals, extend in a similar way to aperiodic materials provided the integral over quasi-momenta is replaced by $\mathcal{T}_{\mathbb{P}}$ and the derivatives $\vec{\nabla}_k$ by $\vec{\nabla}$.

In the independent particle approximation, the electron or holes will be described by a Hamiltonian $H = (H_\omega)_{\omega \in \Omega}$ coming from a Schrödinger operator. The simplest example, for spinless electrons, acts on $\mathcal{H} = L^2(\mathbb{R}^d)$ and is given by

$$H_\omega = -\frac{\hbar^2}{2m} \Delta + \sum_{a \in \mathfrak{A}} \sum_{\vec{r} \in \mathcal{L}_\omega^a} v_a(\vec{R} - \vec{r}),$$

where $\mathfrak{A}$ is a finite set labeling various species of atoms, $\mathcal{L}_\omega^a$ represents the set of positions for the atoms of species $a \in \mathfrak{A}$, and v_a is the atomic pseudo-potential created by atoms of species a acting on the charge carrier. In the *tight binding representation*, the Hamiltonian becomes a matrix indexed by the atomic sites and the corresponding atomic species, acting on $\mathcal{H}_\omega = \ell^2(\mathcal{L}_\omega)$, of the form

$$\langle x, a | H_\omega | y, b \rangle = h_{ab}(t^{-x}\omega, y - x), \quad a, b \in \mathfrak{A}, \quad x \in \mathcal{L}_\omega^a, \quad y \in \mathcal{L}_\omega^b,$$

where h is some continuous matrix-valued function on the set Γ of pairs (ω, x) such that ω belongs to the transversal and $x \in \mathcal{L}_\omega$.

In the harmonic approximation, phonons are described by bosons creations and annihilation operators attached to each atomic site with a polarization index, $a_{\omega, x; a}, a_{\omega, x; a}^\dagger$ such that $[a_{\omega, x; a}, a_{\omega, y; b}^\dagger] = \delta_{ab} \delta_{xy} \mathbf{1}$ whenever $(\omega, x) \in \Gamma$ and a and b are the polarization index (usually varying from 1 to d , if d is the dimension). Then the phonon Hamiltonian, restricted to a finite volume Λ , acts on the boson Fock space of $\ell^2(\mathcal{L}_\omega)$ and is given by

$$H_{\omega; \Lambda}^{(ph)} = \sum_{x, y \in \mathcal{L}_\omega \cap \Lambda} \hbar \kappa_{ab}(t^{-x}\omega, y - x) a_{\omega, x; a}^\dagger a_{\omega, y; b} + W_{\omega; \Lambda},$$

where W represents the anharmonic contributions. Here κ can be seen as the matrix elements of a covariant operator $K = (K_\omega)_{\omega \in \Omega}$. The eigenvalues of K are the square of the vibrational mode frequencies allowed to propagate through the solid.

The charge carrier DoS $\mathcal{N}(\Delta)$, in an energy interval Δ , is defined as the number of eigenstates of the charge carrier Hamiltonian describing the charge carrier motions per unit volume with energy within Δ . Similarly, the vibrational density of states (VDOS) in some frequency interval Δ is the number of phonon modes with frequency within Δ . The *Shubin formula* (Bellissard, 1986, 1989, 1992) shows that they are given by

$$\mathcal{N}_{\mathbb{P}}(\Delta) = \mathcal{T}_{\mathbb{P}}(\chi_\Delta(H)) \quad (\text{charge carriers}), \quad \mathcal{N}_{\mathbb{P}}(\Delta) = \mathcal{T}_{\mathbb{P}}(\chi_\Delta(K^{1/2})) \quad (\text{phonons}),$$

where $\chi_\Delta(E) = 1$ if $E \in \Delta$ and 0 otherwise. A useful example of formula expressed with this formalism is the Kubo formula for the electric conductivity in the *relaxation time approximation* (RTA) given by

$$\sigma_{ij} = \frac{e^2}{\hbar} \mathcal{T}_{\mathbb{P}} \left(\partial_j \left(\frac{1}{1 + e^{\beta(H - \mu)}} \right) \frac{1}{\hbar/\tau_{rel} + \mathfrak{L}_H - i\hbar\tilde{\omega}} (\partial_i H) \right), \quad \text{Kubo's formula} \quad (1)$$

where H is the one-particle Hamiltonian, $\mathfrak{L}_H = i[H, \cdot]$, $\beta = 1/k_B T$ is the inverse temperature (k_B is Boltzmann's constant), $\tilde{\omega}$ is the current frequency, τ_{rel} is the inelastic collision time, μ is the chemical potential fixed by the charge carrier density n_{el} as

$$n_{el} = \mathcal{T}_{\mathbb{P}} \left(\frac{1}{1 + e^{\beta(H - \mu)}} \right) = \int_{-\infty}^{+\infty} d\mathcal{N}_{\mathbb{P}}(E) \frac{1}{1 + e^{\beta(E - \mu)}},$$

Prodan (2017) has developed a computational program based on the principles of noncommutative geometry, showcasing several applications to quantum Hall effect and topological insulators. It allows to numerically compute correlation functions, to estimate the errors due to various approximation schemes. These algorithms converge extremely fast to the thermodynamic limit.

To illustrate this method, an application to the integer quantum Hall effect is provided by Roche et al. (1997) and Prodan (2017), which was probably the first example of accurate numerical calculation of the Hall conductivity from a realistic model of electron in magnetic field, in a disordered medium at various temperatures. In Fig. 5, σ_{xx} and σ_{xy} denote, respectively, the direct conductivity and the transverse conductivity with respect to the current flow in a Hall sample. This figure describes the transition from Chern number 0 to Chern number 1, corresponding to an insulator-metal transition. As can be seen from Fig. 5, there is a fix point seen in the transverse conductivity as temperature varies. This property was later understood through a singularity in the current-current correlation function (Prodan and Bellissard, 2016; Prodan, 2017).

Fig. 5 The simulated (A) σ_{xy} and (B) σ_{xx} , as function of the Fermi level E_F at different temperatures T . The *dashed line* in panel (A) represents the Chern number. The marker sizes (black rectangle) corresponding to $k_B T = 0.01$ reflect the actual statistical errors. The inset (C) shows the flow of σ with T (extracted from Roche et al. (1997)).

Exponents

The main reference here is Bellissard (2002). The main difference between periodic and aperiodic solids can be seen in the electron energy spectrum or in the phonon vibrational spectrum (at least for short wavelength). The band spectrum can be a Cantor set, at least in 1D or near the ground state if the dimension is higher. The electrons can be localized (Anderson localization) or can have exotic long distance behavior. The phonon spectrum is likely to have a large low energy optical band exhibiting quantum chaos. Various scaling exponents classify such a behavior. The *spectral exponents* are associated with the DoS, VDoS, or the *local density of states* (LDoS). The *diffusion exponents* are associated with the motion of a typical wave packet in space.

The DoS (or VDoS) regularity is characterized by its behavior as the size $|\Delta|$ of the energy or frequency interval goes to zero, namely, $\mathcal{N}(\Delta) \sim |\Delta|^d$. Such a definition is ambiguous and, even in computer simulations, difficulties in interpreting results can be overwhelming. The symbol $\sim$ should then be defined as follows: if $f(\varepsilon)$ is a positive decreasing function of $0 < \varepsilon < 1$ (or $1 < \varepsilon < \infty$) then

$$\alpha^* = \lim_{\varepsilon \downarrow 0} \star \frac{\ln f(\varepsilon)}{\ln \varepsilon}, \quad \text{denoted by } f \stackrel{\varepsilon \downarrow 0}{\sim} \varepsilon^{\alpha^*},$$

where $\star$ stands for *sup* (or $+$) or *inf* (or $-$) and similarly if $\varepsilon \uparrow \infty$. Therefore the DoS exponent (and similarly for the VDoS) is defined by

$$\mathcal{N}_{\mathbb{P}}([E - \varepsilon, E + \varepsilon]) \stackrel{\varepsilon \downarrow 0}{\sim} \varepsilon^{d_{\text{DOS}}^+}.$$

The LDoS, also called the *spectral measure*, is defined as follows: if $H = (H_\omega)_{\omega \in \Omega}$ is the one-particle Hamiltonian for the charge carriers, the LDoS $\mu_{\omega, \phi}$ relative to the quantum state $|\phi\rangle$ and its *spectral exponent* $d_{\omega, \phi}^\pm(E)$ are defined by

$$\mu_{\omega, \phi}([E - \delta, E + \delta]) := \int_{E-\delta}^{E+\delta} d\mu_{\omega, \phi} = \frac{1}{\pi} \Im \int_{E-\delta}^{E+\delta} dE' \langle \phi | (E' - i0^+ - H_\omega)^{-1} | \phi \rangle$$

$$\stackrel{\delta \downarrow 0}{\sim} \delta^{d_{\omega, \phi}^\pm(E)}.$$

Whenever Δ is an interval of energy and if $\star = \sup$ (resp. $\inf$), $d_{\omega, \phi}^{\star}(\Delta)$ will be infimum (resp. supremum) over $\Delta' \subset \Delta$ of the supremum (resp. infimum) over $E \notin \Delta'$ of $d_{\omega, \phi}^{\star}(E)$'s, where $\int_{\Delta'} d\mu_{\omega, \phi} = 0$. Then $d_{\omega}^{\star, \pm}(\Delta)$ will be the supremum (resp. infimum) over the state $|\phi\rangle$ of the $d_{\omega, \phi}^{\star}(\Delta)$'s. It turns out that $d_{\omega}^{\star, \pm}(\Delta)$ is independent of ω with probability one and the common value is called $d_{\text{LDoS}}^{\star, \pm}(\Delta)$. In all cases

$$d_{\text{LDoS}}^{\pm}(\Delta) \leq d_{\text{DOS}}^{\pm}(\Delta)$$

The LDoS is *absolutely continuous* (ac) on an interval Δ whenever for almost all $E \in \Delta$, there is $0 < C(E) < \infty$ such that $\mu_{\omega, \phi}([E - \delta, E + \delta]) \leq C(E)\delta$. The Radon–Nykodym theorem implies the existence of an integrable function F such that $\mu_{\omega, \phi}(dE) = F(E)dE$. (Here dE is called the Lebesgue measure.) In such a case, $d_{\omega, \phi}^{\star}(E) = 1$ on Δ so that $d_{\omega, \phi}^{\star}(\Delta) = 1$. The LDoS is *pure point* (pp) on Δ if it can be

written as a sum of Dirac measures $\mu_{\omega,\phi}(dE) = \sum_i \delta(E - E_i) dE$. In such a case, the E_i are eigenvalues and $d_{\omega,\phi}^*(E_i) = 0$ on Δ , implying $d_{\omega,\phi}^*(\Delta) = 0$. The LDoS is *singular continuous* (sc) if $\mu_{\omega,\phi}([E - \delta, E + \delta]) \downarrow 0$ as $\delta \downarrow 0$ for all $E \in \Delta$ and if there is almost no $E \in \Delta$ for which $\mu_{\omega,\phi}([E - \delta, E + \delta]) \leq C(E)\delta$ with $0 < C(E) < \infty$. In particular, if $0 < d_{\omega,\phi}^*(\Delta) < 1$, then the LDoS is sc on Δ .

A charge carrier moving in the solid is a quantum wave interfering with itself after colliding with atomic nuclei. The resulting effect of too many reflections is a slowing down of its motion so that the distance it goes after time t behaves like

$$r(t) \stackrel{t \uparrow +\infty}{\sim} t^{\bar{\beta}},$$

where $\bar{\beta}$ is called a *diffusion exponent*. Like for the case of spectral exponents, there are many ways of defining $\bar{\beta}$. If $\vec{R}$ is the position operator for the charge carriers, then $\vec{R}(t) = e^{itH/\hbar} \vec{R} e^{-itH/\hbar}$ denotes the position after time t , and $|\vec{R}(t) - \vec{R}|$ is the distance that the particle goes during this time. To measure it, it is convenient to select particles having energy in some interval Δ and prepared in the quantum state located at the origin of space, denoted by $|0\rangle$. Since the system is not translation invariant, it is better to average over the choice of the origin (using $\mathbb{P}$). To avoid meaningless time oscillations, it is also convenient to average over time too, leading to the following formula

$$(L_{\Delta, q}(t))^q = \int_{-t}^{+t} \frac{ds}{2t} \int_{\mathbb{X}} d\mathbb{P}_{tr}(\omega) \langle 0 | \Pi_{\omega, \Delta} |\vec{R}(s) - \vec{R}|^q \Pi_{\omega, \Delta} | 0 \rangle \stackrel{t \uparrow +\infty}{\sim} t^q \bar{\beta}_q^*(\Delta),$$

where $\Pi_{\omega, \Delta}$ projects on eigenvalues of H_ω located in Δ . The extra parameter q gives information about the distribution of distances in the initial state.

The diffusion exponents permit to classify the motion of the charge carriers (or of the phonon modes) according to their values. In a periodic crystal, it is known that $\bar{\beta}_q^*(\Delta) = 1$ for all q 's because the motion is *ballistic*. On the opposite side, in an Anderson insulator, where all states are localized, $\bar{\beta}_q^*(\Delta) = 0$. In general $0 \leq \bar{\beta}_q^*(\Delta) \leq 1$ and $\bar{\beta}_q^*(\Delta)$ increases with q . The value $q = 2$ is special and is amenable to experimental measurements. There are situations for which $\bar{\beta}_2 = 1/2$ in particular in weakly disordered systems or if *quantum chaos* occurs: this is *quantum diffusion*. It is important to notice that such a diffusion is not due to some loss of information, but the net result of quantum interferences in a complex environment. The motion is called *subballistic* if $1/2 < \bar{\beta}_2 < 1$ and *subdiffusive* if $0 < \bar{\beta}_2 < 1/2$.

These exponents are related by the *Guarneri inequality* (here, d is the space dimension)

$$\bar{\beta}_q^*(\Delta) d \geq d_{\text{LDOS}}^*(\Delta). \quad \text{Guarneri's bound} \quad (2)$$

Thus, in dimension $d = 1$, *ac* spectrum implies (quasi) ballistic motion. In higher dimension, for any $\varepsilon > 0$, it is possible to find models of Hamiltonians with *ac* spectrum and diffusion exponent smaller than $1/d + \varepsilon$. In particular *ac* spectrum is compatible with quantum diffusion for $d \geq 2$.

Conductivity

For the results here see Bellissard (2002). One of the most striking consequence of the previous scaling analysis is the behavior of the conductivity at low temperature. The classical *Drude formula* asserts that the conductivity of a metal is given by

$$\sigma = \frac{e^2 n_{el} \tau_{rel}}{m^*} \stackrel{\tau_{rel} \uparrow +\infty}{\sim} \tau_{rel}, \quad \text{Drude formula}$$

where m^* is the effective mass of the charge carriers and τ_{rel} is the typical relaxation time for collisions. In view of the RTA Kubo formula (1), the scaling analysis leads to

$$\sigma \stackrel{\tau_{rel} \uparrow +\infty}{\sim} \tau_{rel}^{2\beta_F - 1}, \quad \text{anomalous Drude formula} \quad (3)$$

where $\beta_F = \bar{\beta}_2^*(E_F)$ is the diffusion exponent for $q = 2$ at the Fermi level E_F . The inelastic relaxation time increases as the temperature goes to zero so that (i) if the motion is ballistic or subballistic, then the solid behaves like a conductor; (ii) if the motion is diffusive, then there is a *residual conductivity* at zero temperature; and (iii) if the motion is subdiffusive, the solid behaves like an insulator. In the former case (metallic), the addition laws for conductivity show that if several relaxation mechanisms coexists, the one with the shortest relaxation time will dominate (Matthiessen rules). On the contrary in the latter case (insulating), the one with the longer relaxation time will dominate. In most situations, the dominant dissipative mechanisms come from the phonon–electron collisions in two possible forms: (i) direct collisions leading to the Bloch law $\tau_{rel} \sim T^{-5}$ as $T \downarrow 0$ (ii) electron–electron interactions through the lattice (BCS term) leading to the Landau Fermi liquid theory with $\tau_{rel} \sim T^{-2}$. While in the metallic case the Fermi liquid theory applies, the Bloch law dominates in the insulating case leading to $\sigma \sim T^{5(1 - 2\beta_F)}$. If, as computer simulation suggests for 3D-quasicrystals, $.35 < \beta_F < .40$, it provides a mechanism for the results shown in Fig. 1 (AlPdRe-compound).

Another striking numerical observation is that at *small energy scale* and for *finite volume*, the level spacing distribution of eigenvalues for quasicrystalline lattices follows the Wigner–Dyson law: some *quantum chaos* occurs, namely, the effective Hamiltonian behaves like a *random matrix*. Such a feature is likely to be *universal* in aperiodic media. If so, analysis provided for weakly disordered systems should apply then leading to a quantum diffusive regime at small energy or a long time scales and,

consequently, producing a residual conductivity at low temperature as shown for the *AlPdMn* compound in Fig. 1. But it might be an artifact of the finite volume. However, following an argument by Thouless, used in disordered systems, it follows that (i) the time it takes for the particle with diffusion exponent β to reach the boundary of a sample of size L is $t_{Th} \sim L^{1/\beta}$ (called the *Thouless time*), and (ii) the time it takes for the particle to realize that the spectrum is actually discrete due to the finite volume is given by the Heisenberg principle $t_H \Delta E \approx \hbar$ where $\Delta E \sim L^{-d}$ is the average level spacing so that $t_H \sim L^d$ (called the *Heisenberg time*). If $\beta > d$ then, the particle reaches the boundary too fast and therefore it will dominantly see the effect of the finite volume, namely, of the Wigner–Dyson level spacing distribution. If, on the other hand $\beta < 1/d$, the particle has never the time to reach the boundary so that it behaves like if only the subdiffusion was allowed. Hence

$$\beta_F < \frac{1}{d} \Rightarrow \sigma \stackrel{T \downarrow 0}{\sim} T^\gamma, \quad \beta_F > \frac{1}{d} \Rightarrow \sigma \stackrel{T \downarrow 0}{\sim} \sigma_0 > 0.$$

The Guarneri inequality (2) predicts a *sc* spectrum near the Fermi level in the former case while the latter is compatible with *ac* spectrum if $d > 2$. It is reasonable to expect that a slight change in the hopping parameters of the effective tight-binding Hamiltonian between atomic sites due to chemical constraints (e.g., by changing *Mn* into *Re*) might produce such a drastic change in behavior in Fig. 1.

Abstract

After a brief introduction into aperiodic crystals and one of the most often used experimental methods to investigate their dynamics (inelastic neutron scattering (INS)) the phonon and phason dynamics of the three most often met aperiodic crystals, incommensurate modulated structures, incommensurate composites and quasicrystals are discussed separately.

Key points

Incommensurate modulated structures: dispersion: of amplitudon and phason branches. Incommensurate composites: Phonon dispersion a phason diffusion. Quasicrystals: Phonon dispersion, generalized density of states, phason flips and long wavelength phason diffusion.

Introduction

Crystals with aperiodic structure are solids with long-range order (LRO) in the atomic positions but no translational invariance of a unit cell position. Their Fourier module consists of sharp diffraction spots, proving their LRO, which includes a long-range bond orientational order (BOO). The wave vectors Q of these diffraction spots can be represented by the sum over integer multiples of a number of rationally independent basis vectors, k , which span the Fourier module of the aperiodic crystal

$$Q = \sum_{i=1}^n m_i k_i. \quad (1)$$

In contrast to periodic crystals, where the number of rationally independent basis vectors is equal to the dimension of the crystal (and of its periodic reciprocal lattice), for aperiodic crystals n exceeds the dimension of the space, in which the crystal is embedded. The minimal necessary number of independent basis vectors defines the “rank” of the Fourier module, which is finite in the quasiperiodic case. In a space of dimension n (the n -dim space), the crystal structure, aperiodic in three-dimensional (3D) Euclidean space, can be presented as a “periodic” structure with a unit cell, which usually has a relatively simple structure. Generally, the aperiodic structure can be obtained by an appropriate intersection of the n -dim periodic structure with the physical space, in which the aperiodic structure is observed. For quasicrystals (QCs), this intersection involves the intersection of the n -dim lattice with the physical space, which has an “irrational” slope relative to the orientation of the n -dim lattice. After a small change of this slope to a

rational value, this intersection will lead to a crystal in physical space, which is periodic, but locally has a structure similar to the QCs. Such crystals are called “approximants” (to the corresponding QCs), the dynamics of which are discussed below as well.

Incommensurably modulated crystals, incommensurate composites, and QCs all belong to the aperiodic crystals. However, in some of their fundamental properties, they are different from each other. Therefore, the restriction to one or the other of them is mentioned explicitly as has just been done for QCs. Assuming that the physical (direct, external, or parallel) space, by which the n -dim space is intersected, is 3D, the remaining $(n - 3)$ -dimensional subspace is the “internal” or “perpendicular” (perp) space, which in the case of an incommensurably modulated crystal can be viewed as containing the information on the phase of the modulation function with respect to the original commensurate lattice, out of which the incommensurate phase developed. In view of the atomic dynamics, it is important to realize that the additional dimensions belonging to the internal space can be interpreted as additional degrees of freedom not present in periodic crystals.

In n -dim space, the information about the atomic positions (density distribution) in the aperiodic structure in physical space is “stored” in $n - 3$ dimensional hypersurfaces, for QCs called “atomic surfaces.” The aperiodic structure is the intersection of the physical space with this periodic array of hypersurfaces. It depends on the shape of these atomic surfaces, and the consequences a shift of the physical space in the direction of the internal space will have on the aperiodic structure after the intersection: for continuous surfaces, it just results in a phase change of an incommensurate modulation. For disjunct atomic surfaces, as, for example, in the case of QCs, it leads to sudden changes of the atomic distribution, all of which, however, have the same energy. Thus, the ground state is infinitely degenerated. Likewise, a slow change of the modulation phase does not cost energy.

The Fourier module of the n -dim lattice is a periodic reciprocal n -dim lattice with sharp diffraction spots. This is the space in which inelastic scattering experiments are done to investigate the atomic dynamics. For incommensurate crystals, the 3D reciprocal space can be constructed on the basis of three reciprocal basis vectors. For QCs, which also contain rotation axes other than two-, three-, four-, and sixfold, one obtains the physical reciprocal space by a projection of the n -dim reciprocal space on the physical reciprocal space. Again, $n - 3$ reciprocal lattice components belong to the reciprocal perpendicular space, and are usually called Q_{perp} . As the 3D projection plane in the n -dim reciprocal lattice has to have the same irrational slope with respect to the n -dim reciprocal lattice as the intersection in the n -dim real space had, all Bragg peaks of the n -dim reciprocal lattice will be projected into this hyperplane, as there is no mutual “shading” of different reflections because of the irrational slope. Thus, the Fourier module in this case consists of a dense set of Bragg reflections. In principle, this leads to infinitely many overlapping Brillouin zones and correspondingly to infinitely many gaps in the dispersion curves. Fortunately however, most of the Bragg peaks have an immeasurably small intensity and can therefore be neglected, leading to a diffraction pattern with a finite number of intense Bragg (for fssingle crystals) or Debye–Scherrer peaks (for polycrystals), the intensity of which is highest for peaks stemming from Bragg peaks in the n -dim Fourier module with smallest Q_{perp} . This fact enables the definition of pseudo-Brillouin zones (PBZs) next to reciprocal lattice points with highest Bragg peak intensity and dispersion relations for phonon and phase modes.

The dynamics of aperiodic phases has been studied most often by neutron inelastic scattering (NIS). Special questions such as the amplitudon mode and the central peak have been investigated by light scattering, and some experiments have also been done by X-ray inelastic scattering (XIS).

As aperiodic crystals usually contain more than one type of scatterer and different scatterers couple differently to the used probe, in all cases the total dynamic structure factor, $S(Q, \omega)$, was determined. For samples with n elements this is the weighted sum of the $n(n + 1)/2$ partial dynamic structure factors, $S_{i,j}(Q, \omega)$, where the weights are given by the coupling strength to the probe (here NIS is used as an example in the following equation and consequently the scattering length b) and the atomic concentration c of each of the n elements

$$\sigma S(Q, \omega) = 4\pi \sum \sum b_i b_j c_i c_j S_{i,j}(Q, \omega) + \sum \sigma_i^{\text{inc}} c_i S_i^S(Q, \omega) \quad (i, j = 1, \dots, n), \quad (2)$$

where σ are σ^{inc} are the total and the incoherent scattering cross sections and S_i^S is the self part of the dynamic structure factor of the element i . Alternatively, the single-particle motions can be investigated via the generalized vibrational density-of-states (GVDOS), which again is the weighted sum of the partial density-of-states of each element in the sample, weighted by the strength of the coupling of this element to the scattered probe (here for neutrons again)

$$G(\omega) = \frac{\sum w_i c_i g_i(\omega)}{\sum w_i c_i}, \quad (3)$$

$$w_i = \frac{e^{-2W_i} \sigma_{\text{sc}}^i}{M_i}. \quad (4)$$

Here, e^{-2W_i} is the Debye–Waller factor and M_i is the mass of the scatterer i . The density-of-states (DOS), as always, contains the information on the single-particle dynamics of the system, while the dynamic structure factor reflects also the collective atomic dynamics for coherent neutron scatterers, as is needed for measurements of dispersion relations.

In what follows, the vibrational modes (propagation and displacements in external space in the n -dim representation) and the phason modes (propagation in external space, displacements in internal space) of the three most often met aperiodic crystals, incommensurate modulated structures, incommensurate composites, and QCs are discussed separately.

Incommensurate modulated structures

Incommensurate modulated structures (Currat and Janssen, 1988) are crystal structures in which the atoms in the originally periodic lattice in the normal (N) phase have been displaced by a periodic (static) modulation function in the transition from the N to the incommensurate (I) phase, the period of this modulation being incommensurate with the periodicity of the original lattice. For a 3D crystal, Eq. (1) can therefore be rewritten as

$$Q = ba^* + kb^* + lc^* + \sum_{i=4}^n m_i k_i, \quad (5)$$

where the first three terms describe the reciprocal lattice of the 3D basic (periodic) average structure, and a^* , b^* , c^* , and k_i are rationally independent. In reciprocal space, these structures (and with this also their dynamics) are characterized by a reciprocal lattice which contains the Bragg peaks of the original periodic lattice plus satellites from the incommensurate modulation. Due to the fact that incommensurate structures often form as a consequence of frustration caused by competing interactions, the incommensurate phase normally exists only within a certain temperature (and pressure) range, which is bounded by two transition temperatures, T_1 and T_c . $\Delta T = T_1 - T_c$ is, in some cases, only a few degrees wide, can, however, also extend down to $T_c = 0$ K. If $T_c > 0$ K, the wavelength of the modulation locks-in at T_c onto a rational fraction of the underlying (the main) lattice periodicity, either in a strongly discontinuous manner or by disappearance of phase defects. In contrast to this, the transition into the incommensurate phase at T_1 is a second-order phase transition with a well-defined order parameter. From the viewpoint of the atomic dynamics, this transition from the periodic basis structure to the aperiodic modulation is normally associated with the softening of a phonon branch and the appearance of a Lorentzian shaped central peak at zero energy, part of which is most likely of dynamical origin also. The softening (additional (broad) minimum in the dispersion branches (see Fig. 2)) of the dispersion occurs at a wave vector, which will become the modulation wave vector of the incommensurate phase as is shown in Fig. 1.

For continuous modulation functions, theory (excluding the influence of defects) predicts a softening down to a zero-frequency mode, with a finite phason gap for interruptions of the continuity of the modulation function by defects. Experimentally, the soft mode branch finishes at T_1 with a finite frequency, which however, because of the strong overdamping of the soft mode, often cannot be resolved in NIS experiments. In the I-phase, this branch will then split up into two branches, the “amplitudon” (acoustic like) and the “phason” branches, the latter being related to a continuous shift of the modulation function with respect to the lattice. Near T_c , discommensurations (see below) develop which always lead to a finite gap for the phason mode, called “phason gap.” The intensity of the acoustic modes is proportional to the intensity of the Bragg peak or satellite reflection at the Γ -point. This enables the identification of the phason mode, which is too intense for being an acoustic mode at the (weak) satellite reflection. In addition, the slope of the phason dispersion is lower than that of the lowest acoustic mode. The corresponding dispersion relations are shown in Fig. 2.

While the amplitudon branch will increase with decreasing temperature (normal hardening of the acoustic phonons on temperature decrease), the phason energy may be temperature independent, as has been demonstrated for $(\text{ClC}_6\text{D}_4)_2\text{SO}_2$, for

Fig. 1 Mode softening in ThBr above the transition into the incommensurate modulated phase at T_1 . Approaching T_1 from higher T , the modes show a frequency decrease next to the modulation wave vector $q_s = 3.1 \text{ nm}^{-1}$, which arrives close to $\omega = 0$ in the I-phase.

Fig. 2 Phason and amplitudon branches next to the incommensurate modulation vector at 3.1 nm^{-1} in ThBr below T_i .

which the phason gap ($\sim 80 \text{ GHz}$) could be resolved. The temperature dependence of the width of the modes $\Gamma(T)$ is expected to be approximately the same for all three modes, which meet at the incommensurate modulation wave vector q_s .

The theoretical description of the atomic dynamics of the incommensurate phases often makes use of the periodicity of the corresponding crystals when lifted into n -dim space or applies models for the incommensurate structure in real space. Most of the experimental results for incommensurate modulated crystals have been modeled very successfully using the discrete frustrated Φ^4 (DIFFOUR) model near the phase transition, where the modulation amplitude is still small. At temperatures well below T_i , the modulation amplitude may become rather large. As a consequence of this, a transition from a continuous to a discontinuous modulation function takes place, which means that the atomic surfaces are no longer continuous and smooth. This is always the case for QCs, where the atomic surfaces are generally discrete bounded objects. In the other two aperiodic crystals, modulated and composite, however, such a transition, a “discommensuration transition,” may take place, resulting in domains with a structure close to a commensurate superstructure, separated by strongly incommensurate domain walls, sometimes called solitons. In this case, the description of the atomic dynamics has to also take into account a harmonic and nonlinear contributions. This situation was successfully described using the incommensurate version of the Frenkel–Kontorova model.

The transition occurs in metals and insulators for different reasons: in metals, an incommensurability of the Fermi wave vector with the basis lattice periodicity leads to a Peierls instability, which gives rise to the lattice dynamical precursor effects (local softening of the longitudinal acoustic branch) near the ordering vector, $2k_F$. In insulators, the incommensurate structure either results from an intrinsic lattice instability, which corresponds to the “displacive” limit, or from a collective ordering mode in the “order–disorder limit.” In these cases, the corresponding modulation wave vector is not predictable beforehand. Thus, the lattice dynamics is at the origin of these modulated phases.

Incommensurate composites

Different from the crystals with incommensurate modulation, which is the only aperiodic structure, where a dominant “parent” periodic structure persists, incommensurate composites can be imagined to be made up of two (or more) interpenetrating periodic sublattices (Currat and Janssen, 1988), the unit cell parameters of which are mutually incommensurate. Each of these sublattices, modeled by the incommensurate double chain model (DCM), pertain, to a large extent, to their dynamical characteristics as far as phonons are concerned. Thus, for example, two longitudinal acoustic branches have been found in $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$, which consists of two sublattices, one for each subsystem. However, as all aperiodic lattices, they also have phason degrees of freedom, which in this case concerns the phase between the two sublattices, which changes when one sublattice slides against the other, leading to “sliding modes,” as predicted by the DCM. Whether or not these sliding modes have been observed experimentally is still under debate. As in the case of modulated crystals, these simplified descriptions are only valid as long as the interaction between the mutually incommensurate systems is not too strong. It is very likely that phasons are primarily “diffusive” in incommensurate composites, but considerably less experimental information exists on these systems than on the incommensurably modulated phases discussed above.

Quasicrystals

1D, 2D, and 3D QCs have been found, of which the 1D QCs consist of an aperiodic stacking (e.g., in a Fibonacci sequence) of periodic lattice planes. 2D QCs are made up of lattice planes with a quasiperiodic structure with pentagonal, octagonal, decagonal, or dodecagonal point symmetry, which are stacked periodically (El Hor et al., 2003). Finally, 3D quasiperiodic structures have aperiodic lattices with icosahedral point symmetry.

The atomic structure of 2D and 3D QCs is based on “atomic clusters” of 1–2 nm diameter. In 2D QCs, these are cylindrical clusters made up of a stacking of the quasiperiodic lattice planes, neighboring planes often being rotated against one another, often with some “filling” atoms between the clusters. The atomic structure is dense. 3D QCs, the icosahedral ones, can be roughly divided into three classes on the basis of the dominant type of cluster characteristic of their structure: Mackay clusters, Bergman clusters and Tsai clusters (De Boissieu, 2012), where the Bergman clusters are also characteristic of the Frank–Kasper type of periodic crystals with many atoms per unit cell. As 2D QCs are often “relatives” of the icosahedral phases, here these QCs are put in the same category as their icosahedral neighbors. Because the atomic dynamics is dominated by the type of atomic interaction (interaction potential) and the “local” structure, one expects that the type of cluster, which dominates the local environment of the vibrating atom, will influence the phonon dynamics.

Concerning the phasonic motions (displacements in internal space), one distinguishes two possible phasonic modes (apart from the static-phason strain): “phason flips,” which only cause a local change in the phase of the aperiodic lattice by a (mostly collective) jump of a few neighboring atoms, leading to a “violation” of the matching rules of the perfect quasiperiodic lattice. These have to be distinguished from “phasons,” which are collective diffusive modes. These are different from the incommensurate modulated phases due to the fact that QCs always have discontinuous aperiodic modulation because of the discrete bounded atomic surfaces, which cause jumps or discontinuities in the modulation function, when moving in internal space.

Of these structures, up to now, the atomic dynamics of mainly icosahedral (i-) and decagonal (d-) QCs has been investigated using NIS, XIS, and X-ray intensity correlation techniques. On single crystals, using crystal spectrometers, dispersion curves for acoustic phonons and some low-lying optic branches have been measured. On polycrystalline samples, bands at intermediate energies and the GVDOS have been determined by time-of-flight (TOF) spectroscopy for several metastable and nearly all stable quasicrystalline samples from the total dynamic structure factor, which one measures in all these cases. For i-AlCuFe also, the Fe partial density-of-state was measured using XIS and ^{57}Fe substitution. Quasielastic neutron scattering (QENS) was used on polycrystalline samples and an AlPdMn single crystal to measure phason flips and X-ray diffraction, and correlation techniques to investigate diffusing phasons in QCs. In the following, results from these four types of investigations will be discussed starting with the vibrational degrees of freedom in physical space.

Phonon dispersions

Very characteristic for all phonon branches investigated so far is the important width of the phonon peaks in the measured spectra as soon as the modulus q of the wave vector $\mathbf{q}$ of the measured excitation exceeds a certain critical value, which essentially in all cases is $\sim 3\text{--}4\text{ nm}^{-1}$ (Quilichini, 1997). The broadening of the peaks is of such an importance that the rapidly increasing width prevented measurements of excitations above energies of $\sim 6\text{--}8\text{ THz}$, even though the vibrational density-of-states (VDOS) often extends to twice that energy.

As an example, Fig. 3 shows some of the transverse acoustic branches measured with an AlPdMn single crystal along the twofold direction, the Γ point ($q = 0$, starting point of the dispersion) being one of the strongest Bragg peaks in this crystallographic direction. As the intensity of the inelastic structure factor is proportional to the intensity of the Bragg peak at the Γ point, and only next to a strong Bragg peak the PBZ is well defined, this choice is essential for the result of the experiment.

Fig. 3 already demonstrates this very characteristic property of the lattice dynamics of QCs: the rapid damping of the lattice vibrations as soon as the wavelength of the excitation is smaller than $\sim 2\text{ nm}$, which in several cases is just the approximate diameter of the building unit. Corresponding results have also been obtained by computer simulations of icosahedral QCs, which show above the acoustic dispersion branches, rather dispersionless broadbands of optic modes, as they have also been found experimentally in some cases, and at even higher energies quasicontinuous spectra, which cannot be resolved in single excitations any more. This fact has limited so far the investigation of single excitations to energies below 8 THz, that is, to about half the upper energy limit of all vibrational excitations.

As is shown in Fig. 4, for icosahedral QCs one finds “isotropic” dispersion branches for longitudinal and for transverse phonons, as these crystals, due to the high symmetry of the icosahedral structure, have—in the hydrodynamic limit—only two phonon elastic constants (plus two phason elastic constants and a phonon–phason one). This has also been proven experimentally for the sound velocity. In contrast, the sound “absorption” is anisotropic because of phonon–phason coupling.

For 2D QCs, computer simulations had predicted some anisotropies concerning lattice modes with polarization vectors in the aperiodic plane and in the periodic direction, respectively. However, experimentally the differences observed for d-AlCoNi (Mackay-type) single crystals using NIS are much less important and not far outside the error limits of the experimental results. Likewise, the gap structure of the dispersions, predicted for aperiodic lattices especially in low dimensions, has not clearly been confirmed experimentally up to now.

Fig. 3 Spectra of transverse phonons measured by NIS at a strong Bragg peak in the twofold direction of an i-AlPdMn single crystal (Mackay type). The rapid increase of the phonon line width for $q > 4 \text{ nm}^{-1}$ is obvious. The line width increases roughly proportional to q^2 .

Fig. 4 Dispersion of longitudinal and transverse phonons in i-AlLiCu (Frank–Kasper type) proving the isotropy of each of these excitations with respect to the three different crystallographic axes (twofold, threefold, and fivefold).

Above the acoustic branches, very few dispersionless branches of very broad excitations have been measured by NIS on single crystals by triple axis spectrometry (TAS) and extracted from $S(Q, \omega)$ measured on TOF spectrometers. Both results are in good agreement. These excitations have been suggested to have the character of optic modes.

The phonon dispersions of QCs have been investigated in the accessible energy range (up to 4 THz in all cases, up to 6 THz for few examples, and up to 8 THz in one case) for most of the thermodynamically stable QCs using single crystals and mostly NIS and, in some cases, also XIS.

Generalized vibrational density-of-states

The energy range above 8 THz could be accessed by NIS up to now using only polycrystalline samples and TOF spectroscopy. In this case, one obtains angular-averaged (in reciprocal space) dispersion relations from the shape of the total dynamic structure factor and the GVDOS from its intensity averaged in a reasonably large region of reciprocal space. In order to cover the full energy range, in what follows, the discussion will therefore concentrate more on the GVDOS, which have been determined for most of the thermodynamically stable and several metastable QCs. The GVDOS normally contains several energy bands, the position

(energy of the center of gravity of the band) and intensity of which are usually different for different samples. Thus, it is mainly the shape (and the energy range and the slope at lowest energy (if resolved)) of the GVDOS, which can be used to characterize the atomic dynamics of a sample via the GVDOS.

One obtains considerably more detailed information, if the experimental results are combined with results from computer simulations (CSs). These simulations are based on interactions, which are either calculated directly during the simulation, as is done in the method due to Car and Parrinello, or they are modeled in a more or less realistic manner. The second basic input is a model for the atomic structure, which in the case of QCs is always a structural model for a rational approximant, because of the finite size of the computer model, and it is of similar uncertainty as is the complicated interaction. Because of these inherent uncertainties, the comparison of the results of CSs with those of experiments is “essential” for a judgment on the quality of the simulation results, that is, how realistic these results are. If they are in fairly good agreement, nothing is proved; however, it seems reasonable to use them for the interpretation of the measured results, as they provide very detailed information, which otherwise is possible only with great effort and extensive cost of experiments. In what follows, therefore, the experimental results will be confronted with those from realistic CSs as far as they exist.

Atomic dynamics and cluster structure

As mentioned above, QCs are built from different types of clusters, the structure of which should influence the dynamics as it is the local structure which has the strongest influence on the dynamics. In fact, one finds a difference in the shape of the corresponding GVDOS for the two types of QCs. QCs dominated by more or less complete Mackay icosahedra, such as *i*-AlPdMn, *i*-AlCuFe, and *d*-AlCoNi, seem to have very smooth, nearly structureless one- or two-band spectra, whereas QCs of the Frank–Kasper type, such as *i*-AlLiCu, *i*-ZnMgRE (RE = Ho, Er, . . . , and also Y), and *d*-ZnMgY have more structured spectra with several energy subbands. This is easily seen in a comparison of Fig. 5 with Fig. 7.

CSs suggest that this stronger band structure is due to a stronger grouping of the local vibrational density-of-states (LVDOS), that is, the vibrational spectra of all atoms on different Wyckoff positions in this computer-approximant to the Frank–Kasper type of QCs. This is different in the case of the Mackay type of QCs, where the LVDOS are more different from one another and result in a broad smooth spectrum after summation.

Quasicrystals and their rational approximants

Because one of the basic input parameters for CSs, the structural model, is based on considerable approximations in the case of QCs, quite a few simulations have also been done on periodic crystals with similar chemical compositions as the QCs have, but with a well-known structure. Compared to the atomic dynamics of QCs, the dynamics of these periodic crystals is rather similar to that of the corresponding aperiodic phase if the periodic crystal is an approximant to the QCs. For example, the GVDOS of AlLiCu in the *i*-(Frank–Kasper type) and the periodic R-phase (built up of the same kind of clusters) are very similar to each other, having energy bands at essentially the same energies, but with slightly different intensities. The same results have been obtained in the

Fig. 5 GVDOS of *i*-Zn₆₃Mg_{26.3}Y_{10.7} and *d*-Zn₆₈Mg₄₀Y₂ (both Frank–Kasper type) showing the highly structured distributions with several energy bands and subbands.

measurement of the phonon dispersions of the same alloy system, where also hardly any difference could be detected except for a dispersionless branch at the upper energy limit of this investigation in the case of the i-phase seen in the center of Fig. 4. Likewise, CSs of this alloy system, providing the information on the partial (element specific) dynamical properties, showed a small difference in peak intensity but not in peak position in the calculated GVDOS of the i- and R-phase, respectively. Even more identical results have been obtained for the Mackay type of QCs d-Al_{71.5}Co_{13.5}Ni₁₅ and its modulated approximant Al_{71.5}Co_{15.5}Ni₁₃. In fact, phonon dispersion measurements done on both types of QCs suggest slightly narrower phonon groups for the rational approximant compared with the QCs in the case of the Frank–Kasper type but not in the case of QCs of the Mackay type. These nearly identical results can be understood from the fact that the atomic dynamics is most strongly determined by the local (cluster) structure and potential, which seem to be sufficiently similar for the QCs and their approximants, while their structure differs on the long-range scale. For the 2D QCs just mentioned, this striking similarity of the atomic dynamics was even found at 1000 K, which also means that the thermal expansion (see below) of the QC and its rational approximant are nearly identical. All these conclusions do not apply to periodic crystals of similar chemical composition as the QCs have, but to those which are (structurally) not approximants.

Low-energy modes in quasicrystals

Within the harmonic approximation, which should also apply to QCs at not too high temperatures, at low energies, one expects to find the linear dispersions $\omega = vq$, of transverse (TA) and longitudinal (LA) acoustic phonons, which join the linear dispersions of transverse and longitudinal ultrasound near $q = 0$. Here v is the sound velocity of the mode under consideration ($v = v_T$ or v_L) and q is the corresponding wave vector of the mode. On the basis of the Debye approximation, one therefore expects the phonon density-of-states (PDOS) to start at the lowest energies proportional to $\omega^{(d-1)}$, where d is the dimension of the sample under consideration. For a 3D system with particle density n and a weighted mean value of the sound velocity v , one therefore expects the PDOS to start at the lowest energies proportional to the Debye DOS

$$G_{\text{Deb}}(\omega) = \frac{\omega^2}{2\pi n v^3}, \quad (6)$$

$$\frac{3}{v^3} = \frac{1}{v_L^3} + \frac{2}{v_T^3}. \quad (7)$$

For several—but not all—QCs (and some of their rational approximants), this general rule does not apply either for the measured GVDOS or for the CSs calculated PDOS. One finds a considerably higher intensity in the low-energy region compared to the intensity calculated by using the known sound velocities. Corresponding higher values for these QCs have also been found for the low-temperature specific heat by different groups. Likewise, the temperature dependence of the sound velocity of these QCs shows an unexpected behavior. Investigations of this kind are only possible with thermodynamically stable QCs as normal production defects have to be annealed out before.

Metastable QCs obtained by annealing of a metallic glass show additional low-energy modes stemming from the large grain boundary volume in these samples, as annealing here leads to nanocrystalline samples as has been shown for i-PdSiU and AlCuV. In this case, the intensity of the low-energy modes reaches nearly the level of a well-relaxed metallic glass.

Temperature dependence of the atomic dynamics

The temperature dependence of the dynamics outside the quasielastic region has been investigated most extensively for i- and d-QCs of the Mackay type. In all cases, one finds a considerable shift of the GVDOS to lower energies, that is, an anharmonic behavior of the DOS. However, on quantifying this shift with temperature, for example, with the “integrated” amount of modes shifted (e.g., integration from 0 to 16 or 25 meV) into the low-energy region, one finds a linear dependence of this transfer of modes with temperature up to 1000 K in all investigations, for d-AlCoNi even in the full range of temperatures investigated (up to 1100 K). This linear increase of the shifted intensity is parallel to the shift of the Debye–Scherrer lines in the diffraction diagrams to lower momentum transfers with increasing temperature, caused by the expansion of the lattice. Investigating the shift of lines having contributions only from the periodic axis or only from the aperiodic lattice planes, one observes, for example, in the case of d-Al_{71.5}Co_{13.5}Ni₁₅ that at temperatures above 750 K, the thermal expansion of the QCs in the periodic direction is stronger with increasing T than in the aperiodic plane.

Investigations of the energy dependence of the shifted intensity (by how much has one to shift the intensity of the calculated PDOS to arrive at the experimentally determined GVDOS) show a nearly constant energy shift of $\delta\omega/\omega$ of ~ 6 – 10% at all temperatures analyzed from the upper limit of the GVDOS down to ~ 12 meV. After this, one finds a strong increase of the shifted intensity, becoming more important with increasing temperature and reaching a relative shift of 20% and more. The participation ratio $P(P(\omega) = 1$ if all atoms of the model take part in the mode at frequency ω) shows, in the case of a QC or its approximant, that the smallest participation, that is, the strongest localization of the vibrations takes place at the smallest and highest frequencies.

This is shown in Fig. 6. Correlating this relative frequency shift $\delta\omega/\omega$ with the participation ratio P for the modes at these energies, CSs show that the strongest shifts correlate with the lowest participation ratio. Thus, one has to conclude that a large part of the shifted modes are most likely localized modes. The same CSs clearly demonstrate that the Al atoms contribute more strongly to these shifts than do the TM atoms, as one would expect from the structure, where the TM atoms form a rigid network in the clusters.

Fig. 6 Participation ratio as a function of the energy of the vibrations for the orthorhombic approximant $\text{o-Al}_{13}\text{Co}_4$ to quasicrystalline $\text{d-Al}_{71.5}\text{Co}_{13.5}\text{Ni}_{15}$ in comparison with the chemically comparable but nonapproximant Al_3Ni . The strong decrease of the participation (=localization) of the modes with $\omega < 12$ meV in the case of the approximant is clearly seen.

Fig. 7 GVDOS of $\text{i-Al}_{63}\text{Pd}_{26.3}\text{Mn}_{10}$ (Mackay type) showing the important shift of the GVDOS to lower energies with increasing temperature. The insert demonstrates that the integrated shifted intensity has a linear behavior nearly parallel to the linear shift of the Debye–Scherrer lines in the diffraction diagrams (expansion of the alloy), except for temperatures higher than 1000 K.

For i-AlPdMn, a new phenomenon comes in at temperatures above 1000 K. While one finds essentially the same linear behavior for the integrated intensity and shift of the Debye–Scherrer peaks, as for d-AlCoNi up to 1000 K, the integrated intensity suddenly increases well above this linear continuation (see Fig. 7).

A careful investigation of the total dynamic structure factor of i-AlPdMn in the low-energy region shows that this additional intensity is due to quasielastic scattering being caused most likely by phason flips (see below), that is, a new degree of freedom in addition to the phonon degrees of freedom. As this quasielastic intensity gets considerably broader with increasing wave vector transfers Q , it overlaps with the inelastic region of the spectra and thus contributes to the intensity used to determine the GVDOS.

Phason flips

As the n -dim space corresponding to the structure of the QCs is a “periodic lattice” decorated by disconnected atomic surfaces, any movement of the physical space, with which the n -dim space is intersected, orthogonal to itself will lead to sudden jumps in the atomic positions instead of a continuous change as in the case of a continuous modulation function such as in perfect incommensurably modulated systems. Phason degrees of freedom will, therefore, always concern either flips of atoms in the aperiodic structure, corresponding to a local deviation of the intersection or by a diffusion kind of motion on a much longer timescale.

On the basis of calculations, one expects the phason dynamics to be frozen-in at lower temperatures even in random tilings, where phasons are principally in an unlocked state—in contrast to the locked state in energetically stabilized QCs below the unlocking transition. Only at temperatures well above room temperature, one could expect unlocking and with this, any sign from phason dynamics. Starting from a perfect (decorated) tiling at lower temperatures, phason flips will violate the matching rules and lead to a random tiling, which will be stabilized by its configurational entropy. The reverse mechanism will most likely be incomplete due to kinematic constraints. This process has been studied in several CSs, and at least in one of these investigations, correlated flips of several atoms have been observed.

Experimentally, quasielastic scattering has been found for most of the thermodynamically stable QCs by different groups at temperatures near the upper limit of the existence region of the QCs using polycrystalline samples and TOF spectroscopy. In the case of i-AlCuFe, for example, one obtains a nearly Q -independent width Γ of the Lorentzian fitted to the quasielastic spectrum, Γ being ~ 0.1 meV. This width of the spectrum would then correspond to jumps in the region of $\hbar/\Gamma \approx 7$ ps. The Q -dependence of the integrated intensity of this quasielastic signal with a maximum at 10 nm^{-1} suggests a process localized within a jump distance of 0.4 nm . The most detailed investigation was done at 1073 K using a single crystal of i-AlPdMn on a cold neutron TAS. While the Q -dependence of the quasielastic scattering from polycrystalline samples only allows one to determine the jump distances of the scattering atoms, experiments on single crystals allow, in addition, one to determine the orientation of the jumps. The variation of the measured intensity with the rotational angle in reciprocal space can be best fitted by a model for quasielastic scattering from simultaneous correlated jumps of several atoms in the phason flips. The quasielastic spectra can be fitted with one broad Lorentzian with $\Gamma = 0.7$ meV or (better) with two Lorentzians with $\Gamma = 0.2$ and 0.7 meV. Measurements on the twofold axis now show a maximum of the intensity near 27 nm^{-1} , which corresponds to considerably shorter jump distances than found in the less detailed investigation of i-AlCuFe.

Phason fluctuation in quasicrystals

For reasons mentioned in the previous section, one does not expect to find propagating phason modes as in the case of modulated phases. However, phasons do play a role in the elastic and dynamic properties of QCs. The elastic-free energy of a QC is given by three different terms

$$F = F_{\text{phon}}(\lambda, \mu) + F_{\text{phas}}(K_1, K_2) + F_{\text{cross}}(K_3). \quad (8)$$

Here λ and μ are the Lamé coefficients, K_1 and K_2 the phason elastic constants, and K_3 the phonon–phason coupling term. From investigations of the diffuse scattering, assuming $K_3 = 0$, one can obtain the ratio of K_2/K_1 , which at 300 K was found to be near -0.5 for i-AlPdMn. At temperatures in the range of 1000 K, a diffusive relaxation of phason strain or “phason walls” (left behind a moving dislocation in a QC) can lead to a collective diffusive phasonic excitation or long wavelength phason fluctuations. According to different theoretical investigations performed by several authors, these fluctuations will contribute to the Debye–Waller factor and to the diffuse scattering in a similar way as do phonons and defects, with the exception that the timescales of phonon and phason fluctuations differ by many orders of magnitude, lattice vibrations being in the picosecond range, while the characteristic times for long wavelength phason fluctuations is more between 0.1 and 100 s. Correspondingly, phonons can follow a lowering of the temperature instantaneously, whereas phason fluctuations fall out of equilibrium as a consequence of fast T -changes.

Experimentally, phason diffusion has been investigated in reciprocal space using high-resolution X-ray diffraction to study the phonon and the phason contribution to the Debye–Waller factor in a single crystal of i-AlCuFe in the temperature range between 300 and 1023 K, and to study diffuse scattering from a single crystal of i-AlPdMn as a function of temperature between 300 and 1043 K. Finally, X-ray intensity fluctuation spectroscopy (XIFS) has been used to investigate the time and temperature dependence

of the diffuse scattering from a single crystal of i-AlPdMn at 923 K (Janssen et al., 2002; Francoual et al., 2003). In real space, in situ HRTEM was used to investigate the time-dependent structural changes in d-AlCoCu at 1123 K.

The X-ray diffraction experiment demonstrates a very strong temperature dependence of the phason contribution to the Debye–Waller factor (change by a factor of 9 between 750 and 650 K) and to the diffuse scattering, which decreases with increasing T while the intensity of large Q_{perp} reflections increases. Freezing of the phason dynamics was observed just below 900 K already. The most detailed results were obtained using highly coherent synchrotron radiation in the XIFS experiment. Here, the time evolution of the speckle pattern from diffuse scattering could be directly resolved and a time-dependent intensity correlation $g(Q, t)$ could be determined from the time dependence of the measured intensity

$$F_{\text{cor}}(Q, t) = [1 - \beta g(Q, t)], \quad (9)$$

where β corrects for the partial coherence of the beam. Above 923 K, the expected exponential decay $g(Q, t) = \exp(-t/\tau(Q))$ was found with $\tau(Q)$ proportional to $1/Q^2$, that is, D_{phas} proportional to λ^2 , which proves the diffusive character of the long wavelength phason fluctuation observed, as the width Γ of the spectrum should be $\Gamma = DQ^2 = D4\pi^2/\tau$ for diffusive dynamics. D_{phas} was found to be $1.5 \times 10^{-16} \text{ m}^2 \text{ s}^{-1}$ with the phason excitation wavelength λ between 50 and 100 nm. Again, a very strong temperature dependence was found, τ varying between 60 and 300 s when lowering the temperature from 923 K to 873 K.

A comparable slow phason dynamics was found in the in situ HRTEM investigations of single crystals of d-AlCoCu at 1123 K. The duration for a change of the position of one of the columnar clusters of the decagonal structure was smaller than 10 s, the time between jumps was between 0.1 s and 10 min.

Conclusion

After discussing the phonon and phason dynamics in incommensurate modulated structures and incommensurate composites, phonon dispersions and the generalized vibrational density of states are discussed in more details including the temperature dependence of the atomic dynamics and the strong temperature dependence of the phason dynamics.

Abstract

The unusual electronic transport properties and magnetic properties of quasicrystals are described in terms of the electronic structure of these aperiodically ordered systems. Experimental results for thermopower and conductivity as well as the Hall coefficient are discussed. The electronic density of states is analyzed. Critical electronic states with a multifractal probability distribution are shown.

Key points

- Quasicrystals are aperiodically ordered solids
- Quasicrystal surfaces are themselves quasicrystalline
- Quasicrystals, often composed of elements which are good conductors, show very low electric conductivity
- Thermoelectric powers and Hall coefficients depend crucially on the composition and show anomalies
- Quasicrystals have interesting magnetic properties
- One can interpret quasicrystals as Hume–Rothery solids
- A deep pseudo-gap in the electronic density of states appears at the Fermi level, yielding a strong tendency towards localization
- Electronic states are so-called ‘critical’ states that show a multifractal probability distribution
- The energy spectra of many one-dimensional quasiperiodic systems have neither a continuous part nor a point part but are purely singular continuous
- A hierarchical sequence of clusters of atoms can help to explain the electronic properties

Introduction

Quasicrystals are aperiodically ordered solids (Barber, 2009). Their unusual transport properties, especially the low electric conductivity, are indications of the particular electronic structure of these materials. There are several approaches towards understanding the electronic structure of these systems. Whereas a complete understanding is still lacking, quasicrystals can heuristically be described as Hume–Rothery alloys, which qualitatively accounts for the experimentally observed properties. Other approaches that have been followed are based on the investigation of electrons in aperiodic potentials and on a hierarchical cluster picture of quasicrystals.

Aperiodically ordered solids

Quasicrystals were first discovered in a rapidly quenched AlMn alloy in the early 1980s (Shechtman et al., 1984). For his discovery, Dan Shechtman was awarded the Nobel Prize in Chemistry 2011. Today, many quasicrystalline compounds have been identified, mostly in aluminum or zinc-magnesium based ternary alloys, some of which can be grown to form nicely faceted single crystals of macroscopic size.

The fingerprint of a quasicrystal is a diffraction which consists of Bragg peaks, like for a periodic crystal, but which displays a symmetry that is incompatible with lattice periodicity in three-dimensional space. So far, non-crystallographic symmetries that have been experimentally observed in quasicrystals comprise icosahedral symmetry, featuring axes of two-, three- and five-fold rotational symmetry, as well as dodecagonal, decagonal and octagonal symmetry with a single axis of 15-, 10- or 8-fold rotational symmetry, respectively. Dodecagonal, decagonal and octagonal quasicrystals are periodically ordered along the distinguished axis. In contrast to the icosahedral quasicrystals, such phases show anisotropic physical properties.

The apparent paradox of a Bragg-like diffraction with crystallographically forbidden symmetry can be resolved by interpreting quasicrystals as aperiodically ordered solids (Grimm and Scheffer, 2001; Grimm, 2015). The definition of a crystal has been adapted to include quasicrystals, alongside incommensurate structures, as aperiodic crystals. Their structure is usually described in terms of quasiperiodic tilings (or coverings) of space, which play the role of the lattice in conventional crystals. Quasiperiodic tilings can, for instance, be derived as projections of sections through higher-dimensional periodic lattices. This approach can accommodate the symmetries that are observed in quasicrystals. Structure models consist of decorating the basic building blocks of such tilings with atoms, very much in line with the unit-cell picture of a conventional periodic crystal. For icosahedral quasicrystals, this yields a six-dimensional description of the structure, for the quasicrystalline phases with one periodic axis the analogous description of a quasiperiodic plane requires at least four space dimensions, and the positions of the Bragg peaks can be indexed accordingly. Direct evidence for the structure is furthermore obtained by high-resolution electron microscopy and atomic force microscopy. While there exist sophisticated structure models for various quasicrystals, many important questions remain unanswered, for instance concerning inherent disorder in the structure such as stochastic occupancy of atomic sites, or how the quasicrystalline structure actually grows (Häussler et al., 2003). A detailed discussion of the structure of quasicrystalline alloys is given by De Boissieu (2005).

Due to the aperiodic structure of these materials, important concepts used in conventional crystals, such as the notion of a Brillouin zone, do not strictly apply for quasicrystals. However, in many cases there are, albeit often less precisely defined, analogues of these concepts, such as the pseudo-Brillouin or Jones zone. This zone is constructed from the main structural peaks, it is nearly isotropic in quasicrystals and, in contrast to the case for amorphous alloys, is a sharply defined polyhedron.

Quasicrystal surfaces

Many of the experimental techniques used to probe electronic properties of quasicrystals, such as photoemission experiments, are surface sensitive, because the escape depth for elastic electrons is of the order of a few nanometers. Therefore, it is important to know something about the surface structure in order to interpret the experimental results of such measurements.

There has been a long discussion about quasicrystal surfaces, with results depending on the preparation of the surface. However, as a result of progress in experimental techniques, both concerning the preparation of quasicrystalline samples and the image resolution of electron microscopy, it appears to have been established that quasicrystal surfaces, prepared by sputtering in ultra-high vacuum and suitable annealing, are themselves quasicrystalline and can be understood as a termination of the bulk structure.

Evidence for this is presented in Fig. 1, which shows a high-resolution scanning tunneling microscopy image of a flat terrace of the fivefold surface of an icosahedral quasicrystal (Papadopolos et al., 2002). This technique measures corrugations in the electronic density at the surface arising from the positions of the surface atoms. As shown in Fig. 1, the pattern obtained for the particular terrace is in good correspondence with a patch of a perfect quasiperiodic Penrose tiling. The matching of the surface structure for this terrace and other terraces with a bulk model of the icosahedral quasicrystal corroborates that the surfaces in this case are consistent terminations of the bulk structure, so there should be no artefacts in experimental measurements due to surface reconstructions.

Transport properties

The particular, nearly isotropic order in quasicrystals, which in a sense is intermediate between that of conventional periodic crystals and amorphous systems, is reflected in unusual electronic properties (Berger, 1994). Quasicrystals, despite being composed of elements which in their pure form are good conductors, show very low electric conductivity which decreases with temperature and also with the structural perfection of the quasicrystal. So their behavior is not at all metallic; it is rather reminiscent of a system at a metal-insulator transition, with no energy gap but zero conductivity at zero temperature.

An example is the icosahedral phase in the Al-Pd-Re system, which shows extremely high resistivity at low temperatures, up to $10^6 \mu\Omega \text{ cm}$, with a very strong temperature dependence — the resistivity at a temperature of 0.3 K being about 100 times as large as that at 300 K.

Fig. 1 $75 \text{ \AA} \times 75 \text{ \AA}$ segment of a scanning tunneling microscopy image of a terrace of an icosahedral Al-Pd-Mn quasicrystal surface with a superimposed patch of a perfect Penrose tiling of edge length $7.8 \text{ \AA}$. Reprinted with permission from Papadopolos Z, Kasner G, Diehl RD et al. (2002) Bulk termination of the quasicrystalline five-fold surface of $\text{Al}_{70}\text{Pd}_{21}\text{Mn}_9$. *Physical Review B* 66(184207): 1–13. Copyright 2002 American Physical Society.

Other transport properties also show interesting phenomena (Poon, 1992). Examples are large thermoelectric powers and Hall coefficients that depend crucially on the composition, and may even undergo sign changes as the temperature is changed. Though these transport properties partly resemble those of amorphous phases and crystalline complex metal alloy phases of similar composition, the anomalies appear to be particularly pronounced in quasicrystals. For instance, the residual conductivity appears to be the lowest and the thermopower the largest for the ‘optimal’ quasicrystal composition, to an extent that such properties, alongside diffraction, are often used as an indicator for the structural perfection of quasicrystals.

An example of an in-situ measurement on a thin film is presented in Fig. 2. It shows that, while the temperature dependence of the conductivity is similar in the amorphous and icosahedral phase, the transition to the quasicrystal is accompanied by a strong decrease in conductivity and increase in thermopower, and the low-temperature conductivity in the quasicrystal is nearly zero after several hours of heat treatment (Haberkern, 2002).

Experimental values of the conductivity $\sigma_{4\text{K}}$ at a temperature of 4 K are in the range of a few tens to a few hundred $(\Omega \text{ cm})^{-1}$. The increase in conductivity with temperature is well described by a relationship of the form $\sigma_{4\text{K}} = A(\sigma_{300\text{K}} - \sigma_{\text{M}})$, which shows that the low-temperature conductivity could vanish even for a finite conductivity at temperature 300 K. Experimentally, σ_{M} turns out to be around $150 (\Omega \text{ cm})^{-1}$ for high-quality icosahedral quasicrystals. Given that the actual values for $\sigma_{300\text{K}}$ are in the range of $200\text{--}500 (\Omega \text{ cm})^{-1}$, this indicates that these materials are not far from a metal-insulator transition.

For the Hall effect, the temperature dependence can reasonably well be reproduced by a description of the Fermi sphere with electron and hole pockets. In a simple two-band model of free electrons, a change in composition can affect the balance between electrons and holes, and thus account for changes in the sign of the Hall coefficient. Within this picture, the Hall coefficient provides information about the matching between the Fermi surface and the pseudo-Brillouin zone. Similar comments apply to the strong variations and sign changes observed in the temperature dependence of the thermopower, which appear to be correlated to changes in the Hall coefficients and hence might also reflect the sign of majority carriers in the alloy.

Magnetic properties

One might expect quasicrystals to show interesting magnetic properties. The reason is that most aluminum-based quasicrystals contain a fair amount of transition metals, and there is a class of magnesium-zinc-based quasicrystals containing rare earth atoms, which provide strong localized magnetic moments. However, no long-range magnetic order has been observed in these quasicrystals to date.

In aluminum-based quasicrystals, it appears that only a low fraction of the transition metal atoms in the quasicrystal actually have magnetic moments. One often finds rather small paramagnetic susceptibilities; structurally perfect quasicrystals tend to show

Fig. 2 In situ measurements of the thermopower (left) and conductivity (right) of an initially amorphous AlPdRe thin film during heat treatment and formation of the quasicrystalline (qc) phase. Arrows indicate reversible and irreversible branches. Reprinted with permission from Haberkern R (2002) Electronic transport properties of quasicrystalline thin films. diamagnetic behavior, and there appears to be a correlation between diamagnetism and high resistance in the samples. The situation is somewhat different in quasicrystals containing rare earth elements. Though there had been early reports on an antiferromagnetic ordering in these quasicrystals, these results could not be confirmed and have presumably been caused by the presence of conventional crystalline phases in the samples. However, spin-glass freezing transitions have been observed at relatively low temperatures.

The recent discovery of stable binary icosahedral quasicrystals in rare earth and cadmium compounds (Goldman et al., 2013) provides quasicrystalline materials with localized magnetic moments, and hence a new model system for attaining a deeper understanding of the nature of magnetic interactions in aperiodic structures. So far no long-range order has been found in these systems (Kong et al., 2014). However, both ferromagnetic (Hiroto et al., 2013) and antiferromagnetic (Kim et al., 2012) order have now been observed in low-order approximant phases.

The theory of magnetic point and space groups of quasicrystals is discussed by Ron Lifshitz in this Encyclopedia.

Electronic density of states

To date, the transport properties and the electronic structure of quasicrystals have not been completely understood. Experimental results for aluminum-based quasicrystals such as AlPdMn, which is unique in that it has both icosahedral and decagonal phases, clearly indicate that hybridization between the aluminum sp states and the transition-metal d electrons plays an important role, which is sensitive to details of the local atomic environments.

There is a rather general heuristic picture that interprets quasicrystals as Hume–Rothery solids (Mizutani, 2011). The idea behind this is that there exists a strong interaction between the structure and the electrons, and that quasicrystals occur precisely when the number of electrons available to the system is such that the Fermi surface in momentum space closely matches the pseudo-Brillouin zone. The matching gives rise to a resonant scattering between the conduction electrons and the static structure, leading to a deep pseudo-gap in the electronic density of states and a stronger tendency towards localization at the Fermi level. Thus it offers an explanation why the above-mentioned anomalies of the transport properties are more pronounced in quasicrystals.

This heuristic argument, in combination with the hybridization effects mentioned above, can account for the qualitative behavior of transport properties and their dependency on the composition of the alloy, and has also been supported by experimental and theoretical investigations. It also provides an explanation for the stability of quasicrystals and their existence at

Fig. 3 Ab initio electronic density of states for the 1/1 cubic approximant of the icosahedral AlCuFe quasicrystal, as obtained by the atomic-sphere approximation to the linear muffin-tin orbital method (ASA-LMTO). The Fermi energy ε_F is indicated by a dashed line. Figure courtesy of H. Solbrig (Chemnitz).

certain compositions, because the pseudo-gap formation reduces the energy of the occupied states close to the Fermi energy, and thus lowers the total energy (Krajčí and Hafner, 2002).

An example of an ab initio calculation of the electronic density of states for aperiodic approximant of an icosahedral quasicrystal, i.e. a cubic system with very similar short-range ordering as the quasicrystal, is presented in Fig. 3. It clearly shows a pronounced pseudo-gap feature close to the Fermi energy (Solbrig and Landauro, 2003).

Experimentally, the electronic density of states has been investigated by X-ray emission (XES) and absorption (XAS) spectroscopy (Fournée et al., 2002). Fig. 4 shows an example of experimental results for the aluminum partial density of states in pure face-centered cubic (fcc) aluminum and in icosahedral AlCuFe quasicrystals. Clearly, the aluminum valence band is shifted towards higher binding energies, an effect caused by the strong sp-d hybridization in the alloy. In addition, the observed conduction band is much flatter in the quasicrystalline alloy than in pure aluminum. Together, this leads to a depletion of available states at the Fermi

Fig. 4 Occupied Al 3p and Al 3s, d (left side of the figure) and unoccupied Al p (right side of the figure) spectral distributions in fcc Al (upper set of curves) and icosahedral Al-Cu-Fe (lower set of curves). Changes in the shapes of the spectral curves from fcc Al to the icosahedral compound emphasize that the quasicrystal is no longer a free electron system. Fig. 5 Intensity plot of angle-resolved photoemission spectra for AlNiCo valence electrons for photon energy 95 eV, obtained after mapping the angle into momentum $k_{\parallel}$. The dashed line indicates the parabolic band-like character of the sp-derived states. Reproduced with permission from Rotenberg E, Theis W, Horn K, Gille P (2000) Quasicrystalline valence bands in decagonal AlNiCo. *Nature* 406: 602–605. Copyright 2000, Macmillan Magazines Ltd.

energy, as seen in Fig. 4, and thus an experimental verification of a pronounced pseudogap at the Fermi energy, in accordance with the majority of experimental results (Belin-Ferré, 2002).

However, as shown in Fig. 5, angle-resolved photoemission experiments on decagonal AlCoNi revealed free-electron-like behavior of the sp and d bands, with d bands crossing the Fermi energy (Rotenberg et al., 2000). This indicates that, even though the density of electronic states may still be very low at the Fermi energy, there might be quasi-free electronic states that can contribute to electronic transport.

While these results point to a well-defined sharp Fermi surface, previous experimental attempts to investigate the Fermi surface using the de Haas-van Alphen effect have not been very successful. There has been one published report on de Haas-van Alphen oscillations in quasicrystals, but these results have so far remained unreproduced. In other investigations, quantum oscillations have not been found. However, this does not rule out that they exist, but the effects may be small due to a rather short mean free path of the electrons.

Photoemission experiments (Chiang et al., 2019) of an oxide quasicrystal, which is not a Hume-Rothery alloy, also revealed metallic behavior.

The nature of the electronic states

From a theoretical point of view, the particular aperiodic order present in quasicrystals should affect the nature of electronic states in such systems (Sire, 1994). On the one hand, in a conventional, periodic crystal, there are extended Bloch states, and conduction electrons can move freely through an idealized perfect crystal. This allows for electronic transport, so the system is a conductor, as long as the Fermi energy lies within a band of electronic states and not in a gap. In a three-dimensional system, this property is not destroyed by weak disorder. In a strongly disordered system, on the other hand, one expects the electrons to be localized at energetically favorable positions, and the system behaves as an insulator.

In quasicrystals, apart from the periodic direction in dodecagonal, decagonal and octagonal phases, there are no extended Bloch waves due to the aperiodicity. Waves do not propagate easily, the diffusion of wave packets in neither ballistic nor diffusive (Mayou, 1994). There exists a competition between the aperiodicity, which tends to localize the electron, and the repetitivity of the structure (the same structural motives appearing over and over again), which tends to have a delocalizing effect because electrons can tunnel between identical local environments. The result is that in simple model Hamiltonians one usually observes electronic states that are neither extended over the entire system nor exponentially localized, but are so-called ‘critical’ states that show a multifractal probability distribution (Grimm and Schreiber, 2003). Fig. 6 shows an example of such a probability distribution which was obtained for a model of an electron moving on the Penrose tiling, which is a planar aperiodic tiling of decagonal symmetry (Repetowicz et al., 1998).

A recent investigation (Grimm and Römer, 2021) of the level-spacing statistics showed that the spectral properties can be described by the Gaussian orthogonal ensemble typical for metallic behavior, but no criticality.

For large classes of one-dimensional quasiperiodic systems, it can be shown in a mathematically rigorous way that the corresponding energy spectra have the unusual property that they contain neither a continuous part nor a point part, but are purely singular continuous (Damanik, 2000). Roughly, this means that the density of states is a fractal structure, such as a Cantor set, and the integrated density of states is a ‘devil’s staircase’. These rather strange spectral properties of discrete aperiodic Schrödinger operators provide another hint at the origin behind the particular behavior of quasicrystals.

However, the angle-resolved photoemission results mentioned above indicate the presence of quasi-free electronic states. The data, however, cannot rule out that these eigenstates are critical which might explain the weakness of the band-like emission observed in the quasicrystal when compared to that for periodic crystalline materials.

The role of clusters

Finally, there has been an attempt to explain the electronic properties by using a cluster-based picture of quasicrystals. This acknowledges the arguably important role of local clusters of atoms in quasicrystals. According to this approach, the quasicrystal structure is described in terms of a hierarchical sequence of clusters of atoms making up larger superclusters of clusters and so on. Such a hierarchical structure leads to a density of states that has spiky, self-similar features.

Whereas clusters are definitely important features of the local structure of quasicrystals, the assumption of a hierarchical cluster structure appears somewhat artificial, however, and leads to strange consequences, such as the presence of holes in the structure. Therefore, the validity of this approach appears limited, though it does predict an asymmetry of the density of states at the Fermi energy, which is in accordance with the experimental results.

Conclusion

The electronic structure of quasicrystals continues to be an active and controversially discussed topic of current research. While we now have a reasonable qualitative picture of some important aspects, the electronic structure is still not completely understood. Any progress is intimately linked to a better understanding of the structure formation and growth of quasicrystals, and of the theory of electronic transport in aperiodically ordered solids.

However, current experiments lead to an improved knowledge of the actual structure and the amount and type of inherent disorder, and it is conceivable that a more coherent picture of the electronic structure of these fascinating materials will emerge in the near future.

Abstract

The vibrational excitations of disordered solids differ appreciably from those of crystals. The reason for this anomalous behavior can be traced to the absence of the lattice symmetry, i.e., to the structural disorder. We review the experimental findings and simulational results of the vibrational spectrum of disordered solids, in particular of glasses. We further give an overview of the existent pertinent models and theoretical treatments for explaining the vibrational anomalies, in particular the enhancement of the vibrational density of states with respect to the Debye law (“boson peak”).

Key points

- Glasses, and in general disordered materials, are defined by the lack of long range structural order that gives rise to a complex phenomenology in their vibrational properties.
- The thermal motion of atoms and molecules in glasses cannot be simply described in terms of the wave-like oscillations known to solid-state physicists as phonons.
- From a macroscopic point of view, this complexity is reflected in anomalies that appear in the thermal and transport properties of glasses as well as in their density of states, all of which distinguish amorphous materials from their crystalline counterparts.
- Aims of the present chapter are
 - presenting the macroscopic phenomenology peculiar of the glassy materials;
 - summarize the main techniques for the microscopic determination of the vibrational properties in disordered materials;
 - discuss the main theories capable of explain the experimental findings.

Introduction

The vibrational excitations of disordered solids, in particular of glasses, have attracted the attention of experimental (Baldi et al., 2011; Buchenau et al., 1984, 1986; Chumakov et al., 2004; Foret et al., 1997; Leadbetter, 1969; Monaco and Giordano, 2009; Pan et al., 2021; Sette et al., 1998; Wuttke et al., 1995; Zeller and Pohl, 1971) and theoretical work (Buchenau et al., 1991; Derlet et al., 2012; Franz et al., 2015; Ganter and Schirmacher, 2010; Götzke and Mayr, 1999; Gurevich et al., 2003; Jäckle, 1981; Karpov et al., 1983; Laird and Schober, 1991; Léonforte et al., 2006; Marruzzo et al., 2013a; Maurer and Schirmacher, 2004; Mayr, 2009; Mizuno et al., 2013a; Monaco and Mossa, 2009; Parisi, 2003; Schirmacher, 2006; Schirmacher et al., 1998, 2007; Schirmacher and Ruocco, 2022; Shintani and Tanaka, 2008) (to cite only a few at the beginning) in the last three-quarter century. In crystals the

harmonic vibrational excitations – the phonons – can be satisfactorily described by the symmetry properties of the lattice (Ashcroft and Mermin, 1976). In modern crystalline-lattice dynamics investigations (Monacelli and Mauri, 2021), therefore, the emphasis is on anharmonic effects. On the other hand, in disordered solids, due to the absence of the lattice symmetries, even the theoretical descriptions of the harmonic vibrational excitations poses a challenge. Scientific efforts facing this challenge are still a very active part of condensed-matter research.

Density of states (DOS)

In a solid the harmonic part of the potential energy, i.e. the part, which is bilinear in the displacements $\mathbf{u}_i(\mathbf{r}, t)$ (where i denotes the center of mass of a molecule) can be written as $E_{\text{pot}} = \sum_{ij} \frac{1}{2} \mathbf{u}_i \tilde{D}_{ij} \mathbf{u}_j$ with the dynamical (or Hessian) matrix

$$D_{ij}^{\alpha\beta} = \frac{\partial}{\partial r_i^\alpha} \frac{\partial}{\partial r_j^\beta} E_{\text{pot}}(\mathbf{r}_1, \dots, \mathbf{r}_N). \quad (1)$$

The DOS is then given by

$$g(\omega) = \frac{1}{3N} \left\langle \sum_{\mu=1}^{3N} \delta(\omega - \omega_\mu) \right\rangle, \quad (2)$$

where the eigenfrequencies ω_μ are the square-roots of the eigenvalues $\lambda_\mu = \omega_\mu^2$ of the dynamical matrix, and N is the number of atoms/molecules.

We have started our review of vibrational excitations in disordered solids by introducing the dynamical matrix and the corresponding DOS, because this concept remains valid going from crystalline to amorphous solids. Concepts like Bloch's theorem, leading to dispersion relations in reciprocal space are not valid in the absence of crystalline order, but the DOS, the normalized histogram of eigenfrequencies, can be considered for any type of arrangements of the atomic or molecular sites $\mathbf{r}_i$. This is the reason, why most of the experimental and simulational efforts dedicated to the vibrational spectra of glasses¹ are aimed at finding out the DOS, i.e. the vibrational spectrum of the material.

The boson peak

A paradigm for the anomalous vibrational features of glasses is the so-called boson peak (BP), which is an enhancement of the DOS with respect to Debye's $g(\omega) \propto \omega^2$ law. The latter transforms to a T^3 law for the temperature dependence of the specific heat $C(T)$ (Ashcroft and Mermin, 1976). In contrast to Debye's $C(T) \propto T^3$ prediction, in glasses at low temperatures, $C(T)$ behaves completely in a different way. At very low temperatures, in the range around ~ 1 K, $C(T)$ varies almost linearly with temperature (Lasjaunias et al., 1975; Zeller and Pohl, 1971), and the thermal conductivity (which is orders of magnitude smaller than that of crystals) quadratically (Beekman and Cahill, 2017; Cahill and Pohl, 1989; Lasjaunias et al., 1975; Zeller and Pohl, 1971). This behavior has been successfully ascribed to bistable states in the amorphous structure, between which quantum-mechanical tunneling becomes possible (tunneling states, two-level systems (Anderson et al., 1972; Phillips, 1972, 1987; Yu and Leggett, 1988)). At slightly higher temperatures, the specific heat of glasses still does not follow Debye's T^3 law. If plotted as $C_V(T)/T^3$ one observes a broad maximum around 10 K, see the upper panel of Fig. 1. In the same temperature regime, the temperature variation of the thermal conductivity exhibits a pronounced shoulder, as is shown in the lower panel of Fig. 1. It seems likely that this deviation from Debye's $C(T) \propto T^3$ law must be due to a deviation of Debye's $g(\omega) \propto \omega^2$ law for the DOS. Indeed, in Raman spectra, which – in some way (see below) – represent the DOS, a broad continuum in the ~ 50 cm⁻¹ ($\cong 1.3$ THz) range² was found, in a frequency region, where there is no intensity in the corresponding crystal, see Fig. 2. It was further found that the anomalous Raman spectrum of glasses in the frequency range below 100 cm⁻¹ precisely follows the temperature dependence of the boson occupation factor $n(\omega) + 1 = [1 - e^{-\hbar\omega/k_B T}]^{-1}$. For this reason the low-frequency spectral anomaly in the 1 THz range was called “boson peak” (Jäckle, 1981). Shuker and Gammon (1970) argued, that in disordered solids the selection rules for Raman scattering (Berne and Pecora, 2005) do not apply and came up with a formula for the (depolarized = VH) Raman spectrum.

$$I_{VH}(\omega) \propto C(\omega)[n(\omega) + 1] \frac{g(\omega)}{\omega}. \quad (3)$$

Here $C(\omega)$ is the so-called light-vibration coupling coefficient (Jäckle, 1981; Schmid and Schirmacher, 2008, 2009; Viliani et al., 1995; Mazzacurati et al., 1992), which Shuker and Gammon (1970) assumed to be frequency-independent. Now, if the temperature dependence of the Raman intensity is due to the boson occupation factor, the conclusion is that the spectrum $g(\omega)/\omega$ must be *temperature independent*, and that, consequently, the BP anomaly in the DOS must be a *harmonic* effect. This means that the boson peak must be a feature of the harmonic degrees of freedom.³

¹We take “glasses” and “amorphous solids” as synonyms, independent of the preparation process.

²The Raman intensity is usually reported as a function of $\nu/c = \omega/2\pi c$, which has the unit of an inverse length. 32 cm⁻¹ (in the Raman slang “32 wavenumbers”) correspond to $\nu = 1$ THz and to $\hbar\nu = \hbar\omega = 4$ meV.

³Recent theoretical efforts, claiming that the BP anomaly would be of anharmonic origin (Baggioli and Zaccone, 2019), turned out to be mathematically in error (Shvaika et al., 2021).

Fig. 1 Top: Specific heat, divided by T^3 of several materials against temperature T . Bottom: Thermal conductivity of several glassy materials against temperature. Note that, compared to glassy SiO_2 , at $T = 10$ K, the thermal conductivity of α -quartz is 4 orders of magnitude larger (Beekman and Cahill, 2017; Cahill and Pohl, 1989). Top: From Yu CC and Leggett AJ (1988) *Comm. Condens. Matter Phys.* 14: 231. Bottom: From Freeman JJ and Anderson AC (1986) *Phys. Rev. B* 34: 5684.

Fig. 2 Raman spectrum of glassy and crystalline SiO_2 . From Shuker R and Gammon R (1970) *Phys. Rev. Lett.* 25: 222.

Further, in a seminal paper [Buchenau et al. \(1984\)](#), using inelastic neutron scattering, showed a strong deviation of the DOS of SiO_2 glass from the ω^2 law, which, if represented as $g(\omega)/\omega^2$ shows up as a maximum. They identified this with the Raman boson peak, although the Raman (would-be) DOS did not agree to that extracted from the neutron spectra. In order to cope with this discrepancy, one introduced the frequency dependence of the coefficient $C(\omega)$ ([Jäckle, 1981](#); [Schmid and Schirmacher, 2008, 2009](#); [Viliani et al., 1995](#); [Mazzacurati et al., 1992](#)), into the Shuker-Gammon formula (3). Because the deviation of the specific heat of glasses from the T^3 law is due to the boson peak in the DOS, the maximum in the temperature variation of $C(T)/T^3$ of glasses is also called boson peak ([Ramos, 2020](#)).

The boson peak and related vibrational anomalies are observed in most glassy or disordered materials, and almost the entire scientific work on vibrational excitations in glasses has been devoted to uncover the nature of the (harmonic) vibrational wave functions associated with the BP. The present review simply cannot cover the overwhelmingly large amount of literature published on this subject. We just select some key results, indicating in some way or another the origin of the anomaly. In fact, as we shall state in the conclusion, the matter is still highly controversial.

We start (section “Models and suggestions for explaining the BP anomalies”) by enumerating (most of) the suggestions put forward in the past for explaining the boson peak. In sections “Experimental investigations” and “Simulations,” we try to give an overview over the vast amount of experimental and simulational work on the present topic. In the final section “Discussion,” we discuss the present status of the interpretation of the boson-peak-related vibrational anomalies of glasses.

Models and suggestions for explaining the BP anomalies

In contrast to the rather convincing explanation of the linear- T behavior of the specific heat and the T^2 behavior of the thermal conductivity in the ~ 1 K range in terms of bistable tunneling defects ([Anderson et al., 1972](#); [Phillips, 1972](#)) the boson peak (BP) was from the beginning subject to rather diverse modelling, which continues until now. We here give a brief historical overview and refer to the quoted original literature for more details.

- Karpov, Klinger and Ignat’ev ([Karpov et al., 1983](#)) tried to formulate a classical version of the tunneling model, the soft-potential model. This model features a set of structural defects with anharmonic potentials with very small positive and negative quadratic (stiffness) terms. The (renormalized) density of states of such defects can be shown ([Buchenau et al., 1991, 1992](#); [Gurarie and Chalker, 2003](#); [Gurevich et al., 2005](#); [Karpov et al., 1983](#)) to vary as ω^4 , due to a swallow-tail singularity in the classification of catastrophe theory ([Arnold, 1992](#); [Thom, 1989](#)).
- Orbach ([Orbach, 1986](#)) conjectured that glasses (in particular network glasses) might exhibit a self-similar (fractal) structure. Such structures, imbedded in a homogeneous medium at larger scales were known to exhibit a transition from a Debye-type spectrum $g(\omega) \propto \omega^2$ waves (phonons) at low frequencies (large wavelengths) to fractal-type behavior $g(\omega) \propto \omega^{1/3}$ at higher frequencies (“phonon-fracton crossover,” [Alexander and Orbach, 1982](#); [Nakayama et al., 1994](#)). Simulations of percolating networks, which are examples of such imbedded fractal structures ([Nakayama et al., 1994](#); [Yakubo and Nakayama, 1989](#)) indeed showed such a crossover, but, unfortunately, no boson-peak-type enhancement. Furthermore, no traces of self-similar structure were found experimentally in glasses, except in loose structures such as aerogels ([Vacher et al., 2007](#)) or biopolymers ([Mori et al., 2020](#)).
- According to an argument of Ioffe and Regel ([Ioffe and Regel, 1960](#)), (electronic) waves with a scattering mean-free path ℓ smaller than its wavelength cannot exist. This lead Mott ([Mott, 1990](#)) to the conclusion that waves in the presence of disorder, which would produce an attenuation with a mean-free path shorter than the wavelength, become localized by disorder (Anderson-localization, ([Abrahams et al., 1979](#); [Anderson, 1958](#))). This argument was taken over in papers discussing BP-related anomalies ([Akkermans and Maynard, 1985](#); [Elliott, 1992](#); [Foret et al., 1996](#); [Graebner et al., 1986](#)), in which it was conjectured that the anomalies are due to phonon localization ([John et al., 1983](#); [Kirkpatrick, 1985](#)).
- A step forward in the understanding of the BP anomalies was the investigation of disordered-force constant models by making contact with hopping transport in disordered systems. It was noted by [Alexander et al. \(1981\)](#) that the excitation dynamics of a harmonic system of masses m connected with force constants K_{ij} , which obeys an equation of motion

$$m \frac{d^2}{dt^2} u_i = - \sum_j K_{ij} (u_i - u_j) \quad (4)$$

with scalar “displacements” $u_i = u(\mathbf{r}_i)$ can be mapped to a disordered random-walk (hopping) problem by replacing the double time derivative with a single one. [Schirmacher and Wagener \(1989\)](#) noted that the cross-over of the AC conductivity $\sigma(\omega)$ from being frequency-independent to a strong disorder-induced frequency dependence ([Dyre and Schröder, 2000](#)) corresponds in the analogous harmonic force constant system to a cross-over from a frequency independent to a frequency dependent (squared) sound velocity (elastic constant). They realized that this crossover produces a boson peak and corroborated it with calculations by the coherent-potential approximation (CPA) ([Schirmacher and Wagener, 1992, 1993](#)). Using the self-consistent localization theory ([Economou et al., 1984](#); [Vollhardt and Wölfle, 1980](#)), [Schirmacher and Wagener \(1993\)](#) predicted phonon Anderson localization to happen much above the boson peak, near the upper band edge.

- A pathfinding paper on the boson-peak anomaly was published 1992 by S. R. Elliott ([Elliott, 1992](#)). He argued that in an amorphous structure there exists a length scale at which the atomic structure is no more distinct. This length scale is the

Fig. 3 Sketch of a typical radial distribution function $g(r)$ of an amorphous (monatomic) structure, which approaches the decorrelated value $g(r) \rightarrow 1$.

correlation length and describes the decay of the radial distribution function⁴ $g(r)$ toward its decorrelated value 1 (s. Fig. 3). On a scale larger than ξ the material looks homogeneous and isotropic, therefore, so the argument of Elliott, waves with wavelength λ larger than ξ can be supported by the material. Waves with smaller λ become rather strongly scattered, and, with increasing frequency, the vibrational excitation loses gradually its wave character, as formulated by Ioffe and Regel (1960). Converting length scales to frequency scales by the transverse velocity v_T , which is roughly equal to the Debye velocity $v_D = \omega_D/k_D$ (Debye frequency ω_D , divided by the Debye wavenumber $k_D = \sqrt[3]{6\pi^2 N/V} = \sqrt[3]{6\pi^2}/a$, where a is an intermolecular spacing) Elliott (1992) conjectured that the frequency at which disorder-induced deviations from the Debye wave physics should occur near $\omega_B = v_T/\xi \sim \omega_D a/\xi$, i.e. roughly 1/10 of the Debye frequency. This is precisely the frequency range of ~ 1 THz, around which the boson peak is observed in most materials (Pan et al., 2021). A correlation between the boson-peak position and v_T/ξ is indeed observed in many glasses (Duval et al., 1990a; Elliott, 1992; Pan et al., 2021).

- In a model calculation on a 3-dimensional lattice with randomly distribution of force constants Schirmacher et al. (1998) considered a mass-spring system of the type (4) on a simple-cubic lattice with Gaussian force-constant disorder, truncated from below. The model was treated both by CPA and by numerical diagonalization. In Fig. 4 we show their result for the reduced DOS $g(\omega)/\omega^2$. First, the agreement of the CPA with the numerical data showed that the CPA is a reliable mean-field theory for disorder. In both calculations a pronounced BP is visible (Fig. 4). The inclusion of negative force constants demonstrated that the BP is strongly enhanced by the presence of negative force constants and is a precursor of an instability, which occurs in the presence of too many negative force constants. The authors further evaluated the mean-free path $\ell(\omega)$, and found by comparison with the wavelength $\lambda(\omega)$ that the BP position is near the Ioffe-Regel limit, where $\ell(\omega) \sim \lambda(\omega)$. The authors also evaluated the level-distance statistics of the eigenvalues and demonstrated that the vibrational states near and above the BP are *delocalized*, because the statistics follows that of the Gaussian Orthogonal Ensemble (GOU) of random matrices (Mehta, 1991; Stöckmann, 1999). A mobility edge, above which the states are localized, appears only very near the upper end of the band, thus corroborating the predictions of Schirmacher and Wagener (1993). It was proved later in numerical investigations of a similar force-constant model (Pinski et al., 2012a, b) that these states obey the Porter-Thomas statistics (Porter, 1965), i.e., are of the same type as random-matrix eigenstates.
- That in a disordered harmonic system an extended frequency region exists, in which the vibrational states are neither propagating nor localized had already been found by Allen et al. (Allen and Feldman, 1993; Allen et al., 1999; Feldman et al., 1993) in a simulation of amorphous Si. Allen et al. (1999) called the corresponding excitations “diffusons,” because the intensity of such waves obey a diffusion equation like light in milky glass (Ishimaru, 1978). They called the Debye waves below the Ioffe-Regel crossover “propagons” and the localized states near the Debye frequency “locons.” They deliberately avoided the term “phonons,” because phonons are by definition the eigenstates of a crystal.
- A model calculation similar to that of Schirmacher et al. (1998) (a crystal with force-constant disorder) was presented later by Taraskin et al. (2002), but with a somewhat different interpretation. They observed - similar to the findings in (Schirmacher et al., 1998) that - with increasing disorder - the lowest van-Hove singularity⁵ of the lattice broadens, moves down in frequency, and then smoothly goes over to the low-frequency BP. They concluded that the BP is essentially due to the leveling off of the transverse phonon branch and not so much due to disorder. This view was corroborated later by experimentalists who compared silicate glasses with their crystalline counterparts (Chumakov et al., 2011, 2014; Zorn, 2011) (see below).
- Grigera et al. (2003) investigated a disordered mass-spring model (Euclidean random-matrix model, ERM) by a diagrammatic procedure. Inspired by the behavior of a mean-field theory obtained from a class of diagrams, they obtained a BP-type anomaly,

⁴ $g(r) - 1$ is the Fourier transform of the structure factor $S(k)$ minus 1 (Elliott, 1984; Hansen and McDonald, 1986) of the amorphous material, which can be measured by elastic X-ray or neutron diffraction. $4\pi r^2 g(r) N/V$ (particle number N volume V) gives the probability density for the presence of other atoms/molecules with distance r from a given one at the origin.

⁵A Van-Hove singularity occurs in the DOS of a crystal at a frequency, at which the phonon dispersion $\omega(k)$ becomes constant at the Brillouin-zone boundary.

Fig. 4 Reduced DOS $g(\omega)/\omega^2$ versus frequency for Gaussian force-constant distributions with $\sigma/K_0 = 1$ and several lower cutoffs (in units of K_0). The symbols represent the numerical diagonalization, the full lines the CPA results. The agreement is achieved without any adjustable parameters. From Schirmacher W, Diezemann G, and Ganter C (1998) *Phys. Rev. Lett.* 81: 136.

which – with increasing disorder – leads to an instability like the CPA of Schirmacher et al. (1998) with too many negative force constants. This instability was interpreted as a transition from a minima-dominated potential-energy surface (PES) to a saddle-dominated PES. The ERM model was shown to imply Rayleigh scattering, i.e. a sound attenuation $\Gamma(\omega) \propto \omega^4$ (Ganter and Schirmacher, 2010; Grigera et al., 2011; Schirmacher et al., 2019), in agreement to the disordered-lattice calculations (Schirmacher et al., 1998; Taraskin et al., 2002) and the HET theory (see below).

- Schirmacher (2006) formulated a heterogeneous-elasticity theory (HET), which is a theory of elasticity, in which the shear modulus G exhibits spatial fluctuations. This theory was solved for the averaged DOS by field-theoretical techniques for a mean-field theory (Self-consistent Born approximation, SCBA), which predicts:
 - a disorder-induced boson peak independent of an underlying lattice;
 - a disorder-induced Rayleigh-like sound attenuation $\Gamma(\omega) \propto \omega^4$;
 - a minimum of the transverse phase velocity $v_T(\omega)$ near the BP. This theory conforms with the previous conclusions that the BP is a phenomenon produced by the structural disorder of the glass. Within the same theoretical framework a theory for the thermal diffusivity was formulated. Combined with the inelastic scattering from two-level system, he found an explanation for the characteristic shoulder in the temperature dependence of the thermal conductivity: It is an *upside-down boson peak* (see Fig. 5).

Fig. 5 Thermal conductivity calculated in self-consistent Born approximation (SCBA) (Schirmacher, 2006) for three values of the disorder parameter $\gamma \propto \langle (\Delta G)^2 \rangle$, compared with the data of Fig. 1 (Freeman and Anderson, 1986), scaled with the Debye temperature Θ_D . The red arrows correspond both to the boson peak positions of the specific heat, calculated in SCBA as those of the experiments. From Schirmacher W (2006) *Europhys. Lett.* 73: 892.

Fig. 6 Top: $Q(T)/C_D(T) \propto Q(T)/T^3$ against T/θ_D for four different (glassy) alcohols, compared with glassy glycerol. Bottom: $[Q(T) - \gamma T]/T^3$ for three metallic glasses. γT is the Sommerfeld contribution of the electrons. Top: From Ramos MA, Talón C, and Vieira S (2002) *J. Non-Cryst. Sol.* 307: 80. Bottom: From Li Y, Bai HY, Wang WH, and Samwer K (2006) *Phys. Rev. B* 74: 052201.

The anomalous increase of the DOS above the Debye DOS was subsequently shown (Schirmacher et al., 2007) to be related to the Rayleigh ω^4 behavior of the sound attenuation: It was shown that the excess DOS is just proportional to the sound attenuation $\Gamma(\omega)$.

The SCBA version of HET, which only applies to Gaussian distributions of elastic moduli and moderate disorder was generalized by means of an off-lattice version of the CPA, again by field-theoretical techniques (Köhler et al., 2013). This version served recently to obtain a disorder classification of glasses (Pan et al., 2021) (Fig. 6).

- An important aspect in the discussion about the boson peak has been contributed by the theoretical investigation of the jamming transition (DeGiuli et al., 2014a, b; Franz et al., 2015; Liu et al., 2011; O'Hern et al., 2003; Wyart, 2005, 2010, 2012; Wyart et al., 2005). The disordered solid is considered as a random packing of soft spheres with a finite range of interactions. The latter induce a number of constraints, which lead to a finite shear elasticity. The instability of the solid – where the shear stiffness becomes zero – is reached at the isostatic point, where the number of constraints equal the number of degrees of freedom (Maxwell, 1864). It was shown by simulations and effective-medium calculations that in such random packings near the jamming instability a boson peak appears in the vibrational spectrum. This was rationalized by a rather simple mean-field jamming model, the so-called perceptron (Franz and Parisi, 2016; Franz et al., 2015), which was introduced in connection with neural networks. The generic frequency dependence in the mean-field limit (dimension $d \rightarrow \infty$) is given by a modification of the Marchenko-Pastur law of rectangular random matrices (Marchenko and Pastur, 1967)

$$g(\omega) \propto \omega \frac{\sqrt{(\omega^2 - \omega_0^2)(\omega_{\max}^2 - \omega^2)}}{\omega^2 + \omega_*^2}. \quad (5)$$

In finite dimensions the gap below ω_0 is filled with Debye-type waves, so that one has in general (DeGiuli et al., 2014a; Franz et al., 2015)

$$g(\omega) \propto \begin{cases} \omega^{d-1} & \omega \ll \omega_0 \\ \omega^2/\omega_0^2 & \omega_0 \ll \omega \ll \omega^* \\ \text{const.} & \omega^* \ll \omega \ll \omega_{\max}. \end{cases} \quad (6)$$

The resulting boson peak at ω_0 marks – as in the heterogeneous-elasticity theory – the crossover between the Debye wave regime and the random-matrix regime. The eigenvectors of random matrices (Mehta, 1991) are known to be delocalized.

Experimental investigations

Specific heat and thermal conductivity

The specific-heat BP, i.e. a maximum in the temperature variation of $C(T)/T^3$, see the top panel of Fig. 1, is observed in practically all glassy materials. As further examples we display in Fig. 6 boson peaks of a number of alcohols (Ramos et al., 2002) and metallic glasses (Li et al., 2006). In the latter the Sommerfeld contribution due to the free electrons γT , with $\gamma = \frac{1}{3}\pi^2 k_B^2 N(E_F)$ ($N(E_F)$ is the electronic DOS at the Fermi level), must be subtracted, in order to obtain the vibrational contribution. It is interesting to note that in many cases the BP temperature $T_{\max}$ is proportional to the Debye temperature Θ_D .

We mentioned in the introduction (bottom panel of Fig. 1), that in the temperature variation of the thermal conductivity a characteristic shoulder (plateau) is observed near $T_{\max}$. Similar features are observed in other complex solids like oriental glasses (Yoreo et al., 1986), and other disordered crystalline materials (Ackerman et al., 1981; Avila et al., 2006; Cohn et al., 1999; Suekuni et al., 2015; Tachibana, 2015; Tachibana et al., 2008). In all cases the temperature in the middle of the plateau of the thermal conductivity coincides with $T_{\max}$ of the boson peak (Krivchikov and Jeżowski, 2020), as displayed in Fig. 7, where thermal-conductivity data are displayed with a temperature scale normalized with $T_{\max}$.

As mentioned also in the introduction, there is a correspondence between of the vibrational part of the specific heat and the vibrational DOS $g(\omega)$. This relationship is given by (Ashcroft and Mermin, 1976)

$$C(T) = \frac{\hbar^2 \omega^2}{k_B T^2} \int_0^\infty d\omega g(\omega) \frac{e^{\hbar\omega/k_B T}}{[e^{\hbar\omega/k_B T} - 1]^2}. \quad (7)$$

Buchenau et al. (1986) showed for the example of glassy SiO_2 , by comparing with inelastic neutron-scattering data, that the DOS obtained from the neutrons reproduces the temperature variation of the specific heat using (7).

Inverting Eq. (7) for $g(\omega)$ is a mathematically ill-posed problem, but, using methods explained in Tikhonov and Arsenin (2005) (Tikhonov regularization) it can be still achieved, for obtaining the DOS, as shown by Surovtsev (2001). This has been widely used in the meantime (Ando et al., 2018; Pan et al., 2021).

Fig. 7 Temperature dependence of the thermal conductivity of several materials plotted vs. $T/T_{\max}$, where $T_{\max}$ is the maximum of the reduced specific heat $Q(T)/T^3$: SiO_2 (Cahill and Pohl, 1987; Damon, 1973), PMMA and PS (Stephens, 1973), glassy $\text{C}_2\text{D}_2\text{OD}$ (Krivchikov et al., 2011), oriental glass $(\text{KBr})_{0.75}(\text{CN})_{0.25}$ (Yoreo et al., 1986), disordered ferroelectric perovskite crystals (Tachibana, 2015; Tachibana et al., 2008), clathrate semiconductors (Avila et al., 2006; Cohn et al., 1999; Suekuni et al., 2015) and disordered $\text{Y}_2\text{O}_3\text{ZrO}_2$ (Ackerman et al., 1981). The dashed line indicated the (boson) peak of $Q(T)/T^3$. From Krivchikov AI and Jeżowski A (2020) *arXiv:2011.14728*.

Spectroscopic methods

Early investigations

Other than by the temperature dependence of the specific heat, information about the vibrational DOS of a solid can be obtained by several spectroscopic methods: Raman spectroscopy (Berne and Pecora, 2005; Jäckle, 1981), neutron (Schober, 2014), X-ray (Sette et al., 1998), and nuclear (Chumakov and Rüffer, 1998) inelastic scattering as well as Terahertz spectroscopy (Ohsaka and Ihara, 1994; Schmuttenmaer, 2004; Taraskin et al., 2006). In the early times vibrational spectroscopy in glasses was focussed on comparing the obtained spectra with those of their crystalline counterparts. In Fig. 8 we show an investigation the paradigmatic glass silica (SiO_2). The Raman and neutron spectrum of glassy silica is compared with the spectrum of polycrystalline quartz. It is observed that in the regime above $\sim 300 \text{ cm}^{-1}$ –10 THz the spectra exhibit essentially the same features, which correspond to the typical vibrational excitations of a covalent network (Galeener et al., 1983).

Fig. 8 (A) HH and VH Raman intensity of vitreous silica, (B) vibrational density of states $g(\omega)$ of vitreous silica, and (C) $g(\omega)$ of polycrystalline silica, both obtained by inelastic neutron scattering. From Galeener FL, Leadbetter AJ, and Stringfellow MW (1983) *Phys. Rev. B* 27: 1052.

Inelastic Neutron and Raman scattering

For incoherent neutron scattering the scattering intensity is given by the incoherent one-phonon neutron scattering law (Schober, 2014)

$$S_{\text{incoh}}(k, \omega) \propto k^2 [n(\omega, T) + 1] \frac{g(\omega)}{\omega}. \quad (8)$$

Here $\hbar k$ is the momentum transfer and $\hbar\omega$ the energy transfer experienced by the neutrons during the scattering process.

The thermal prefactor $n(\omega, T)$ is due to the condition of detailed balance $S(k, -\omega) = S(k, \omega)e^{-\hbar\omega/k_B T}$. In principle, (8) applies only to *incoherent* neutron scattering, which would limit the investigations mainly to hydrogen-containing materials like glycerol (Wuttke et al., 1995) or water (Mallamace et al., 2015). However, it was demonstrated, that expression (8) may be used for coherent spectra, averaged over all experimentally available momenta $\hbar k$ ("incoherent approximation" (Carpenter and Price, 1985; Fabiani et al., 2008; Oskotskii, 1967; Schober, 2014)).

Let us have a look at the DOS of glassy glycerol and silica, obtained (Wischniewski et al., 1998; Wuttke et al., 1995) by inelastic neutron scattering, shown in Fig. 9. The DOS is plotted as $g(\omega)/\omega^2$, which should be frequency independent if Debye's law would apply. We see that the strong enhancement with respect to the Debye expectation (boson peak) is temperature independent in the low-temperature regime 50 to 150 K. This is again an indication that in this low-temperature regime the boson peak is likely to be of

Fig. 9 Density of states of glasses as evaluated by inelastic neutron scattering. Top: Glycerol, Bottom: SiO_2 . It can be seen that in both cases in the low-temperature region (below ~ 170 K) the boson-peak spectrum is temperature independent. The arrows (top panel) and straight lines (bottom panel) correspond to the Debye $g(\omega) \propto \omega^2$ prediction (Ashcroft and Mermin, 1976). Top: From Wuttke J, Petry W, Coddens G, and Fujara F (1995) *Phys. Rev. E* 53: 4026; Bottom: From Wischniewski A, Buchenau U, Dianoux AJ, Kamitakahara WA, and Zarestky JL (1998) *Phys. Rev. B* 57: 2663.

harmonic origin. The temperature dependence at higher T (or smaller frequency) due to the anharmonic interaction may come about – like in crystalline solids (Götze and Michel, 1974; Horner, 1974; Monacelli and Mauri, 2021) – in two different ways: (i) indirectly via a change of the elastic constants, (viz. the sound velocities) with T (quasi-harmonic effect), or (ii) via a direct change of the excitation spectrum.

Among the many subsequently reported neutron-scattering results on the vibrational spectrum of glasses (Arai et al., 1999; Buchenau et al., 1984, 1986, 1988; Inamura et al., 2001; Reichenauer et al., 1989; Vacher et al., 1989; Wright and Sinclair, 1985; Zanatta et al., 2013; Zorn, 2003) many investigations focussed on the extraction of the Raman-coupling function $C(\omega)$ by comparing the neutron spectra with the Raman spectra (Achibat et al., 1993; Benassi et al., 1991; Duval et al., 1990b, 1993, 1999; Hehlen et al., 2000a; Ivanda et al., 2001; Lannin, 1977; Saviot et al., 1999; Sokolov et al., 1993; Surovtsev, 2001, 2004; Surovtsev et al., 2003, 2004; Surovtsev and Sokolov, 2002a, b; Zemlyanov et al., 1992). All of these showed that $C(\omega) \propto \omega$ in the BP frequency regime is linearly proportional to the frequency ω . This was used subsequently to study the DOS by Raman spectroscopy (Caponi et al., 2009; Corezzi et al., 2013; Deschamps et al., 2012; Hehlen et al., 2000b; Hehlen and Neuville, 2015; Kalampounias et al., 2006; Moriya et al., 2008; Parshin et al., 2006; Rossi et al., 2012; Schulte et al., 2008).

In 2008 Schmid and Schirmacher (2008) published a theory of Raman scattering, which makes it possible to describe Raman spectra and other spectra containing information on the DOS in a unified way. This was used subsequently, in combination with heterogeneous-elasticity theory (Schirmacher, 2006; Schirmacher et al., 2007, 2014; Schirmacher and Ruocco, 2022) to describe and reconcile Raman, neutron-scattering and specific-heat data in a unified way (Benzine et al., 2021; Pan et al., 2021; Schulte et al., 2011; Unruh et al., 2008).

Nuclear inelastic scattering

A powerful method for measuring the vibrational DOS is nuclear inelastic scattering (NIA) (Seto et al., 1995; Sturhahn et al., 1995). It had already been pointed out as early as 1960 by Singwi and Sjölander (1960) that the resonance fluorescence spectrum of Mössbauer impurities essentially gives the same information as the incoherent neutron scattering law. But in conventional Mössbauer experiments or by applying conventional X-Ray sources the frequency range was not extended enough to observe phonon spectra. This situation changed with the advent of high-brilliance ***synchrotron sources, and it was shown (Seto et al., 1995; Sturhahn et al., 1995) that the NIA method can successfully be used to extract phonon spectra of solids. A severe drawback of this method is that there are only a few Mössbauer isotopes available with resonance energies accessible by synchrotron radiation, namely ^{57}Fe ($E_0 = 14.4$ keV), ^{119}Sn ($E_0 = 23.9$ keV), ^{151}Eu ($E_0 = 21.6$ keV). Chumakov et al. (2004) imbedded ferrocene molecules with ^{57}Fe as central atom into several glassy hosts in order to successfully extract the vibrational DOS of the hosts. The authors made sure that the ferrocene molecules were tightly bound into the hosts, so that the spectra are not due to an extra motion of the impurity, but represent the host spectra. In Fig. 10 the results for the vibrational DOS of four glass-forming materials are shown

Fig. 10 Reduced DOS of collective motions in toluene, ethylbenzene dibutylphthalate, and glycerol glasses. Arrows indicate the energy of the boson peak estimated from the data at lowest temperature. From Chumakov AI, Sergueev I, van B  rk U, Schirmacher W, Asthalter T, R  ffer R, Leupold O, and Petry W (2004) *Phys. Rev. Lett.* 92: 245508.

Fig. 11 Comparison of the density of states (A), (D) and the reduced density of states (B), (E) obtained with the nuclear inelastic scattering technique, and of the specific heat (C), (F) for ambient silica glass and α -quartz (A)–(C), and for densified silica glass and α -cristobalite (D)–(F). From Chumakov AI et al. (2014) *Phys. Rev. Lett.* 112: 025502.

(Chumakov et al., 2004). The authors found that all spectra (and further spectra from the literature) exhibited an exponential decrease of the DOS beyond the boson peak. It has been shown recently (Tomaras and Schirmacher, 2013), by applying instanton techniques (Cardy, 1978), that this exponential decrease is a disorder-induced phenomenon like the band tails observed in the electron spectra of disordered materials (Cohen et al., 1988).

Later the NIA method was used to compare the spectra of glassy silicates with the DOS, obtained from the phonon dispersions of the corresponding crystals (Chumakov et al., 2011, 2014; Zorn, 2011). Following the conclusions of the model calculations of Taraskin et al. (2002) the authors substantiated the point of view that the boson peak is a broadened version of the lowest (transverse-acoustic) van-Hove singularity of the corresponding crystal. They explained the fact that in crystals in the low-frequency regime of ~ 1 THz no such singularity occurs by pointing out that glasses usually have a lower density than the corresponding crystals. In the case of SiO_2 they compared the DOS of the ambient SiO_2 glass with that of crystalline α quartz and that of densified SiO_2 glass with that of cristobalite, which has a higher density. In both cases the glassy boson peak is observed near the corresponding van-Hove singularity. The boson peaks in the specific heat of these materials corroborate these findings (see Fig. 11). The authors state the opinion that quite generally in all glassy materials the boson peak would be due to the leveling-off of the transverse acoustic sound dispersion near the quasi-Brillouin zone (quasi-van-Hove singularity), i.e. the BP would in general *not* be caused by the structural disorder. We will comment on this in the discussion section.

Inelastic X-ray scattering

A breakthrough in the vibrational spectroscopy of glasses was the development of inelastic-X-ray spectrometers at synchrotron sources with extremely narrow resolution (Sette et al., 1995, 1998). Due to the very high brilliance of the synchrotron radiation it was possible to devise monochromators and analyzers (using very-high-order reflections) with resolution of ~ 1 meV, comparable

to that of thermal neutron scattering. In contrast to the latter for the X-rays there is no upper kinematic limit in energy. For the neutron investigations it was not possible to investigate acoustical waves above the ~ 1 THz or 4 meV regime. Similar to neutrons, the X-rays are sensitive to the *longitudinal* degrees of freedom.

Instead of averaging over the momenta, as done in the incoherent approximation, the observation of the $\mathbf{k}$ dependence of the spectra can provide useful information on the nature of the vibrational wavefunctions, which underly the observations. The spectra are given by the *coherent* scattering law

$$S_{\text{coh}}(k, \omega) \propto [n(\omega) + 1] \chi''(k, \omega) \quad (9)$$

where $\chi(k, \omega) = \chi'(k, \omega) + i\chi''(k, \omega)$ is the complex dynamical susceptibility, which is usually parametrized as a damped harmonic oscillator (DHO) with resonance frequency $\Omega(k)$ and sound attenuation (damping) coefficient $\Gamma(k)$

$$\chi(k, z) = \frac{k^2}{-\omega^2 + \Omega(k)^2 - i\omega\Gamma(k)} \quad (10)$$

Inelastic scattering experiments featuring a resonance $\Omega(k)$ are usually referred to as Brillouin spectra and $\Gamma(k)$ is then the Brillouin line width (full width at half maximum, FWHM for $\Gamma \ll \Omega$).

Indeed the first inelastic X-ray scattering (IXS) experiments on glassy glycerol (Masciovecchio et al., 1996; Sette et al., 1998), LiCl:6H₂O (Masciovecchio et al., 1996) and SiO₂ (Benassi et al., 1996) revealed a pronounced propagating longitudinal sound excitation, i.e. $\Omega(k) \propto k$ which extends into the $k \sim 5 \text{ nm}^{-1}$ range, which corresponds to a wavelength of $\sim 1 \text{ nm}$. Interestingly, in all cases the propagating wave-like excitations extended beyond the boson-peak energy $E_{BP} = \hbar\omega_{BP}$, as indicated in the top panel of Fig. 12 for the case of glycerol (Sette et al., 1998). Similar features were found in glassy SiO₂ (Benassi et al., 1996).

Fig. 12 Momentum (Q) dependence of the DHO resonance frequency parameter $\Omega(Q)$ and $\Gamma(Q)$, Eqs. (9) and (10), for glassy glycerol. From Sette F, Krisch MH, Masciovecchio C, Ruocco G, and Monaco G (1998) *Science* 280: 1550.

Fig. 13 Upper panel: Dispersions of maxima of the dynamical structure factors obtained by inelastic X-ray and neutron scattering experiments (Baldi et al., 2008 and citations quoted therein). Lower panel, top: Frequency-dependent sound velocity $v_L(\nu) = \Omega_L(q)/q$ vs. $\nu = \Omega(q)/2\pi$, middle: Brillouin line width (sound attenuation) $\Gamma(\nu)$, bottom: reduced DOS $g(\nu)/\nu^2$ obtained by neutron scattering, using the incoherent approximation. From Baldi G, Giordano VM, Monaco G, and Ruta B (2010) *Phys. Rev. Lett.* 104: 195501.

Some authors were astonished that above the boson peak and the Ioffe-Regel frequency propagating modes would exist (Foret et al., 1997; Vacher et al., 1998), but later experiments confirmed the presence of these modes, which proved to be of longitudinal character.

In subsequent times the resolution of the X-ray beam-lines was increased and further details about the vibrational excitations of glasses were revealed. Here, we focus on the example of glassy SiO_2 . In the top panel of Fig. 13 the dispersion $\Omega(q)$ is shown together with the maxima of inelastic neutron scattering (INS) data obtained by the same authors. The latter show the boson peak near $\hbar\omega = 6$ meV as a wavenumber independent feature. Two years later Baldi et al. (Baldi et al., 2010, 2011) found a crossover in the sound attenuation (Brillouin line width) from a Rayleigh-like behavior $\Gamma(\omega) \propto \omega^4$ to ω^2 , as predicted by heterogeneous-elasticity

theory (HET) (Marruzzo et al., 2013a; Schirmacher, 2006; Schirmacher et al., 2007, 2014; Schirmacher and Ruocco, 2022) near the boson-peak frequency $1.5 \text{ THz} \cong 6 \text{ meV}$. This crossover is accompanied by a kink in the frequency-dependent longitudinal sound velocity $v(\omega)$, where $v(\omega) = \Omega(q)/q|_{\omega=\Omega(q)}$, predicted as well by HET theory. Similar findings were obtained as well for glassy glycerol (Monaco and Giordano, 2009) and sorbitol (Ruta et al., 2010). In the latter materials, as remarked by Baldi et al. (2011) the connection between $\Gamma(\omega)$ and $v(\omega)$, as given by HET theory is sufficient to explain the boson peak in the INS data, whereas in glassy SiO_2 it is not. The missing boson-peak intensity could then be additionally due to optic-like or van-Hove-singularity like modes (Baldi et al., 2012, 2016, 2017; Chumakov et al., 2011, 2014, 2016).

Simulations

Since the first molecular-dynamics (MD) simulation of a Lennard-Jones glass⁶ of Rahman et al. (1976), in which the DOS was calculated and was shown to agree to the Fourier transform of the velocity autocorrelation function (Hansen and McDonald, 1986; Schirmacher et al., 2014), a very large number of MD simulations has been published, and, again, we can only mention a few, which – to our opinion – contributed most to the understanding the low-frequency anomalies of glasses.

In the 1970–80 years only limited computer power and storage capacity was available, so the simulated systems could have only particle numbers of $N = 500$ to 2000. In simulations of such small systems Laird and Schober (Laird and Schober, 1991; Schober and Laird, 1991) found low-frequency modes, which, by analyzing the participation ratio appeared to be localized.

The participation ratio p is defined by (Dean and Bell, 1970)

$$p = \left[N \sum_i (\mathbf{e}_i \cdot \mathbf{e}_i)^2 \right]^{-1} \quad (11)$$

of the eigenvectors $\mathbf{e}_i$ of the dynamical matrix (1) normalized as $\sum_i (\mathbf{e}_i \cdot \mathbf{e}_i) = 1$. p takes values of the order unity for extended states and small values of order $1/N$ for localized ones. In macroscopic large disordered materials, as stated above, the low-frequency vibrational excitations are acoustical waves, because the material on a large scale is homogeneous and isotropic. In the systems of only ~ 1000 particles, the low-frequency acoustic waves do not exist, because their wavelengths would be much larger than the sample size. Therefore Laird and Schober (1991) argued that the localized excitations, which they observed at small frequencies, would – in a larger system – hybridize with the acoustical waves (like heavy-mass impurities in crystals (Economou, 1979)), and called these excitations “quasi-localized.” Quite recently a revival of the investigation of such small systems took place in the literature (Angelani et al., 2018; Baity-Jesi et al., 2015; Lerner and Bouchbinder, 2021; Lerner et al., 2016; Mizuno et al., 2017; Paoluzzi et al., 2019; Parisi et al., 2020; Wang et al., 2020). It was found that the DOS of the quasi-localized modes of small systems follows a scaling $g(\omega) \propto \omega^\alpha$, where in many investigated systems $\alpha \approx 4$ (Lerner and Bouchbinder, 2021). In other systems the observed exponent α ranged between 2 and 4, dependent on the preparation protocol (Angelani et al., 2018; Paoluzzi et al., 2019; Parisi et al., 2020).

In the 2000er years the advancement of machine power and storage, in particular the advent of parallel computing (Patterson and Hennessy, 2009) made it possible to treat systems with 10^5 to 10^7 particles, enabling to disentangle the boson peak from the finite-size resonances of the acoustic waves. One of the first of such studies treated a Lennard-Jones system (Léonforte et al., 2005) and glassy SiO_2 (Léonforte et al., 2006). It was shown, confirming other similar findings (Lemaître and Maloney, 2006; Wittmer et al., 2002) that the overwhelming part of the vibrational displacements in a glass do not follow an external strain in an affine way. Instead, these displacements display *non-affine* patterns, as shown in Fig. 14. Léonforte et al. (2006) found that the correlation length ξ of these patterns is as large as ~ 10 interatomic spacings both in the Lennard-Jones and SiO_2 glass. In a representation against $\omega\xi/v_T$ – in accord with the empirical law of Elliott (1992) and Duval et al. (1990a) – the observed boson peaks coincide, as displayed in Fig. 14. Further studies of model glasses focussed on evaluating the local spatial fluctuations of elastic constants. As shown in the two seminal papers of Lutsko (Lutsko, 1988, 1989) local elastic constants – including the non-affine contributions – can be evaluated by a coarse-graining procedure. Such a procedure was applied in a number of papers (Derlet et al., 2012; Marruzzo et al., 2013a; Mizuno et al., 2013a, b). These studies confirmed the presence of spatial fluctuations of elastic constants in glasses, which is the basic assumption of heterogeneous-elasticity theory, HET (Schirmacher, 2006; Schirmacher and Ruocco, 2022; Schirmacher et al., 2014). In fact, using the example of a simulated soft-sphere glass, i.e. a quenched system of $N = 10^7$ particles with interparticle potential varying as $\phi(r) \propto r^{-12}$ Marruzzo et al. (2013a) showed that the observed boson peak is due to the spatially fluctuating elastic constants and can be perfectly described by HET using exactly the observed statistics. The data were evaluated for the DOS $g(\omega)$ from the velocity autocorrelation function and the longitudinal (L) and transverse (T) current correlation functions (Hansen and McDonald, 1986; Schirmacher et al., 2014) $C_{L,T}(k, \omega) = (\omega/k^2) \text{Im} \{ \chi_{L,T}(k, \omega) \}$ with the longitudinal and transverse dynamic susceptibility given by the DHO formula (10). The quantities $\Omega_{L,T}(k)$ and $\Gamma_{L,T}$ were converted to complex frequency-dependent elastic constants $G(\omega)$ (shear modulus) and $M(\omega) = K + \frac{4}{3}G(\omega)$ (longitudinal modulus) as

⁶A Lennard-Jones glass is a liquid, in which particles interact via a Lennard-Jones potential $\phi(r) \propto Ar^{-12} - Br^{-6}$, quenched to a very low temperature.

Fig. 14 Top: Non-affine displacements in a computer SiO_2 glass subject to a global shear; bottom: reduced DOS $g(v)/v^2$ scaled with the transverse sound velocity and the correlation length ξ for the SiO_2 glass and a Lennard-Jones-glass (Léonforte et al., 2005). From Léonforte F, Tanguy A, Wittmer J-P, and Barrat J-L (2006) *Phys. Rev. Lett.* 97: 055501.

$$\begin{aligned}
 G(\omega) &= \frac{\rho m}{k^2} [\Omega_T(k)^2 - i\omega \Gamma_T(k)]_{\omega=\Omega_L(k)} \\
 M(\omega) &= \frac{\rho m}{k^2} [\Omega_L(k)^2 - i\omega \Gamma_L(k)]_{\omega=\Omega_L(k)} \\
 &= K + \frac{4}{3} G(\omega).
 \end{aligned} \tag{12}$$

Here ρ_m is the mass density. The transverse and longitudinal data sets could be reconciled by taking the bulk modulus K frequency-independent and real, as demonstrated in the bottom panel of Fig. 15, i.e. it was found that $\Gamma_L(\omega) = \frac{4}{3} \Gamma_T(\omega)$ and, indeed, $M'(\omega) = K + \frac{4}{3} G'(\omega)$. Furthermore, the prediction of heterogeneous-elasticity theory, HET (Marruzzo et al., 2013a; Schirmacher, 2006; Schirmacher et al., 2007) (blue lines) lie on top of the simulated frequency dependent spectral quantities. This holds for three very different temperatures. It is remarkable that the spatial distribution of the fluctuating local shear moduli, extracted from the simulation, agrees with the distribution used in the theory. The temperature dependence at very low frequencies could be traced to anharmonic effects (Marruzzo et al., 2013b). The downward kink of the real parts of the elastic coefficients at the BP frequency, which correspond to the downward kink of the k dependent sound velocity (Baldi et al., 2011; Monaco and Giordano, 2009), which is predicted by HET, arises as a consequence of the Kramers-Kronig relation between the real and imaginary parts of the complex moduli. Similar features had also been observed in an earlier simulation of a Lennard-Jones glass (Monaco and Mossa, 2009).

Fig. 15 Comparison of the results of a soft-sphere glass simulation (symbols) for three different temperatures $T = 5 \cdot 10^{-5}$, $T = 5 \cdot 10^{-4}$, $T = 5 \cdot 10^{-3}$ (in Lennard-Jones units), with the prediction of heterogeneous-elasticity theory (HET) (Schirmacher, 2006; Schirmacher et al., 2007) (blue lines). Top panel: reduced DOS $g(\omega)/\omega^2$. Bottom panels: Real and imaginary part of the complex shear modulus, obtained from both, the complex transverse and longitudinal sound velocities, see text. From Marruzzo A, Schirmacher W, Fratolocchi A, and Ruocco G (2013a) *Scientific Reports* 3: 1.

Discussion

Let us try to summarize, what has been found in the last half century about the origin of the boson-peak related vibrational anomalies of glasses. Beside that – on the theoretical side – the subject is highly controversial, we find that – on the experimental (and computer-experimental) side – the evidence is that the boson peak is *not universal*, i.e. in different materials the spectral features leading to an enhanced reduced DOS in the THz regime are caused by different physical mechanisms. For the prototypical glass SiO_2 there is clear evidence for the presence of local oscillators in the THz regime, which are most probably librations⁷ of SiO_2 tetrahedra (Buchenau et al., 1984), giving rise to optical modes and van-Hove peaks in the corresponding crystal (Chumakov et al., 2014). On the other hand, in non-network glasses like metallic glasses or the computer models, it has become clear that the structural disorder is responsible for the boson peak. In such materials the BP marks the transition from sound-like vibrational excitations to random-matrix like excitations. It has been demonstrated by investigating the vibrational spectrum of a macroscopic model glass that both features, the disorder-induced boson peak and a smeared van-Hove singularity coexist at different frequencies (Wang et al., 2018). In fact, as remarked by Baldi et al. (2011) both mechanisms might be present in glassy SiO_2 . For a simulated metallic glass Brink et al. (2016) recently demonstrated that the BP clearly comes from the disorder and not from a smeared van-Hove singularity. Particularly difficult in this respect is the interpretation of specific heat data. As stated above, a BP in the specific heat is observed not only in glasses but in an extended number of (complex) crystalline materials (Krivchikov and Jeżowski, 2020). In the latter, they are most probably due to low-frequency “rattlers,” i.e. loosely bound heavy-mass molecules or residues.

⁷The term “libration” denotes the rotational oscillation of a tetrahedron around its center of mass.

Abstract

The structure determination of quasicrystals is presented. After an introduction on quasicrystals, the principles of the superspace crystallography are briefly introduced. This is then illustrated on the structure determination of the CdYb quasicrystal going from data collection to the final models. Other examples are briefly presented. Phason diffuse scattering is introduced in the last section.

Key points

- Introduction to aperiodic crystals
- Quasicrystal a special class of aperiodic crystals
- Presentation of the superspace crystallography for a non-specialist
- Quasicrystals are found in many different systems
- Structure of the binary CdYb icosahedral quasicrystal
- Phason fluctuations, phason elastic constants and diffuse scattering.

Introduction

The atomic structure of condensed matter materials has for long time been described by the ideal periodic crystal model: a unit cell, which repeats periodically towards infinity, is ‘decorated’ by a motif describing the atomic positions within the unit cell. The atomic structure is completely determined by the unit cell symmetry and size, and by its ‘decoration’. Only particular symmetries are compatible with periodicity, leading to the 14 Bravais lattices and 230 different space groups (see ‘Periodicity and lattices’ and ‘Space groups’ articles). For instance, only two-, three-, four- and sixfold rotation axes are allowed, the fivefold rotational symmetry being incompatible with periodicity.

Extremely powerful tools have been developed for solving periodic atomic structures by means of the analysis of the intensity distribution in the X-ray, neutron or electron diffraction pattern and complex structures such as proteins, which contain several thousands of atoms in the unit cell, are now almost routinely determined (see ‘diffraction’, ‘structure determination’ articles). Indeed, if an X-ray (or neutron or electron) beam is sent on a periodic crystal, it is diffracted in specific directions and forms the so-called diffraction pattern. The diffraction pattern of a crystal is best understood through the use of Fourier transforms. The periodic crystal is described as the convolution between a periodic lattice (set of delta peaks) and a motif which describes the atomic

[☆]Change History: June 2023. M. de Boissieu replaced Figures 4, 7 to 14, and 16.

positions within the unit cell. Its Fourier transform (FT), which corresponds to the observed diffraction pattern, is the product of the FT of the lattice and the FT of the motif. The FT of the periodic lattice is also a periodic lattice, the reciprocal lattice. Positions of reciprocal lattice points, indicate the directions for which there is diffraction and are directly related to the Bragg law which relates the lattice plane d -spacing, the reciprocal lattice vectors and the incoming radiation wavelength. The reciprocal lattice has the same point group symmetry as the crystal under study, i.e., if a crystal has a threefold rotation axis the reciprocal space also has threefold symmetry. It follows from this that a fivefold diffraction pattern is 'forbidden,' or more precisely is incompatible with periodic lattice translation. The intensity distribution of the Bragg peaks depends on the atomic decoration of the unit cell and is given by the square of the FT of the 'decoration' or motif. All the structural information is contained in this intensity distribution but cannot be used directly because the phase of the Fourier transform is unknown. Direct methods or phasing algorithms such as the charge flipping, or low-density elimination allow to overcome this 'phase problem.' Phases are determined for the strongest Fourier amplitudes, and Fourier transformed. This allows to derive a starting model which is further refined against the observed Bragg peak intensity distribution.

In most materials departure from this ideal model is present in term of disorder which can be positional disorder, chemical disorder, partially occupied sites, vacancies, dislocations distribution, etc. This disorder gives rise to a supplementary contribution in the diffraction pattern which is smoothly varying in reciprocal space and is named diffuse scattering (Krivoglaz, 1969). When the disorder is not too large (bounded correlation-correlation) the resulting diffraction pattern is the superposition of Bragg peaks with the diffuse scattering. The later gives information on how the defects are distributed in the materials, with possible short range chemical order, distortion or changes in local interatomic distances, etc.

At the extreme, if too much disorder is present, material is described by the glass model in which only short-range order exists: it is characterized by a diffraction pattern in which Bragg reflections no longer exist and presents a smooth variation as a function of the scattering angle.

It is fair to say that most of the physical properties of materials are relying on their periodic description. The Bloch theorem and Brillouin zone boundaries are for instance key 'ingredients' in elaborating the theory of physical properties of condensed matter materials and both rely on the underlying periodicity. When disorder is present it is most of the time treated as a perturbation.

Quasicrystals belong to the large family of aperiodic crystals which encompasses incommensurately modulated phases, incommensurate composites and quasicrystals. All aperiodic crystals are characterized by the presence of long-range order, with Bragg peaks in their diffraction pattern and the absence of periodicity at least in one direction (Janssen et al., 2018). Incommensurately modulated crystals were observed soon after the discovery of the Bragg Laue, first in metallic alloys (Dehlinger, 1927) (Daniel and Lipson, 1942). In this case an ideal periodic structure is modulated by a wave (distortion or chemical) whose wavelength is incommensurate with the ideal structure periodicity. Composite structures are characterized by two interacting subsystems, with two periodicities whose ratio is irrational. They were first identified in the fool's gold $\text{Hg}_{3-8}\text{AsF}_6$ where mercury 1D chains ordered below 120 K (Hastings et al., 1977; Pouget et al., 1978) and in the compound TTF (Johnson and Watson, 1976) where ions form guest chain along the c axis of the TTF host lattice.

Both incommensurate modulated phases and incommensurate composites structures are best understood using the superspace theory developed by P.M. de Wolf, A. Janner and T. Janssen. In this theory the periodicity is recovered in a space of higher dimension than our 3D space (Janssen and Janner, 2014).

In 1984, Shechtman et al. published the electron diffraction pattern of a rapidly cooled AlMn alloy which displayed Bragg reflections and fivefold symmetry axes (Shechtman et al., 1984). This brought a lot of excitement, since two characteristic features of the diffraction pattern, believed to be incompatible, were present: long range order, as evidenced by the Bragg peaks, and fivefold symmetry. An example of the Laue diffraction pattern of a high-quality Al—Pd—Mn icosahedral quasicrystal is shown Fig. 1: Bragg peaks are sharp and the fivefold symmetry, characteristic of the icosahedron, is clearly visible. The discovery of Shechtman was named quasicrystal and is a new kind of long range ordered matter belonging to the aperiodic crystals' family. Soon after this discovery single grain quasicrystals have been obtained from slow cooling from the melt, establishing quasicrystals as a third class of aperiodic crystals. Besides the icosahedral symmetry, quasicrystals have been obtained in systems which are a periodic stacking of quasiperiodic planes with 8-fold, 12-fold and 10-fold symmetry.

Which system forms quasicrystal?

The first quasicrystalline samples were obtained by rapid quench from the melt and were metastable. As a consequence, only small single grains (less than 1 μm) could be synthesized and the only tool to pinpoint the quasicrystalline character was electron diffraction. Since then a large number of quasicrystalline phases have been discovered, in various systems (Janssen et al., 2018).

A large number of quasicrystals are made of intermetallic alloys Al, Zn or Cd based, such as AlMn, AlPdMn, AlCuFe, AlNiCo, ZnMgSc, ZnMgY, CdYb, AuGeSi . . . (Tsai, 2013). Some of them are stable at room temperature and can be obtained by slow cooling from the melt, or usual growth process such as Bridgman or Czochralski, leading to mm or even cm sized single grain quasicrystals. Their composition range is in general very limited, almost as a line compound. The stabilizing mechanism of intermetallic quasicrystal is far from being understood, but size effects and Hume-Rothery electronic stabilization are believed to play a crucial

role (Janssen et al., 2018; Tsai, 2013). The Fig. 2 displays an example of a single grain of the ZnMgY icosahedral phase obtained by slow cooling from the melt whose facets form a dodecahedron, nicely illustrating the icosahedral symmetry at a macroscopic scale (Inaba et al., 2000). Also shown is a centimeter single crystal of the icosahedral AlPdMn phase obtained by Czochralski growth (Boudard et al., 1995).

The recent discovery of a layer 2D dodecagonal quasicrystal in the Ba—Ti—O system grown on a metallic substrate, has opened the route to possible discovery of oxide quasicrystals (Förster et al., 2013) and demonstrating that intermetallic quasicrystals are not the only possible quasicrystals.

Another large family of quasicrystals, most of them with dodecagonal symmetry, has been synthesized in soft condensed matter such as supramolecular dendrimer liquid crystals, surfactant-coated metallic nanoparticles, mesoporous silica, colloidal copolymer micelles in solution, and ABC star terpolymers and two kinds of linear block copolymers in condensed (Dotera, 2011). In this case the length scale at play is much larger than interatomic distances and is rather of the order of the interparticle distances i.e., 1 nm or larger.

Superspace crystallography and quasicrystals

The understanding of the structure of incommensurately modulated structures has been much improved by the introduction of superspace crystallography by P.M. de Wolf, A. Janner and T. Janssen (Janssen and Janner, 2014). The same approach can be applied to quasicrystals where periodicity is recovered in a space of dimension larger than three. For icosahedral quasicrystals, a six-dimensional space is necessary to recover periodicity. It is beyond the scope of this article to give the details of this approach and we refer to (Janssen et al., 2018) for an introduction.

As an illustration of this procedure, we elaborate in the following on a simple 1-D example: the Fibonacci chain. It is built up with two tiles whose length is in the ratio $\tau/1$, τ being the golden mean (1.618...). The Fibonacci chain can be constructed by a substitution rule $L \rightarrow LS$ and $S \rightarrow L$, where L and S stand for the long and short segment. The resulting 1-D structure is quasiperiodic and has the form $LSLSLSLSLS...$. A compact description of this structure is achieved in a 2-D periodic space, briefly described hereafter. Let us start with a square lattice in a 2-D space. The latter is decomposed in two orthogonal subspaces: the physical space, also called parallel space (E_{par}), and a complementary space called perpendicular space (E_{per} , Fig. 3). The slope of the physical space with respect to the lattice is irrational and is equal to $1/\tau$. The square lattice is decorated with segment lines, elongated along the perpendicular direction, and whose length is equal to the projection of the square onto the perpendicular space. The 1-D quasicrystal is obtained as a section of the decorated periodic lattice by E_{par} : each time the E_{par} line intercepts a segment line, an atomic position is generated. The final result is the Fibonacci chain. The advantage of the high dimensional description is that, since periodicity is recovered, the relationship between direct and reciprocal space can be computed using FT. The indexing of the diffraction pattern can be carried out, and structural modeling and refinement against observed data can be handled. Moreover, all the information on the structure (local environment, interatomic distances, etc.) is now contained in a very compact form with the decorated square unit cell. More complex structures can be generated: for instance, the segment line can be given a longer length: this will generate additional positions in the 1-D quasicrystal. It is also possible to add other segment lines in the square unit cell, which could mimic another atomic species.

This procedure generalizes to the case of 3-D quasicrystals such as icosahedral phases. In this case the higher-dimensional space is six-dimensional and the 6D lattice is hyper-cubic. Segment lines are now 3-D objects called occupation domains or atomic surfaces. The problem of structure determination is that of finding the location and the detailed shape of the occupation domains. Although it might seem a simple task, it is a complex problem, for which only recently satisfactory solutions have been proposed. Indeed, specifying the shape of a 3-D occupation domain requires an infinite number of parameters, and guidelines have to be found for the modeling.

Let us return to the 1-D case and look for the diffraction pattern of the Fibonacci chain. The diffraction pattern can be computed from the FT of the 2-D decorated lattice: this is the product of the FT of the lattice with the FT of the segment line. The 2D reciprocal space is also decomposed into the parallel (physical) reciprocal space and the perpendicular one. As a result of the FT of the decoration which are segment lines, intensities are stronger when the perpendicular component of the reciprocal vector is small as illustrated in Fig. 4. Remembering that the section becomes a projection by FT, the 1D diffraction pattern is obtained by projecting all the points in 2D onto the parallel 1D physical reciprocal space. The 2D diffraction pattern can be indexed by two integer indices, and each reciprocal lattice vector has a component in the parallel space and one in the 'perpendicular' space. This is kept after the projection scheme, and the 1D diffraction pattern is also indexed by two integers. Since the slope is irrational, there is a dense set of Bragg reflections, but only a finite number of them are larger than a given threshold. The procedure is illustrated in Fig. 4.

In the case of the icosahedral phase, six integer indices are necessary for indexing the diffraction pattern: they correspond to the six directions pointing towards the vertices of an icosahedron. The Fig. 5 displays the X-ray diffraction pattern measured along a fivefold axis for the icosahedral AlPdMn quasicrystal. Indexing is carried out with two indices along this specific axis, following a procedure analogous to the Fibonacci chain, but this corresponds to a summarized notation of the real six indices. All Bragg peaks can be indexed un-ambiguously at a position that can be exactly computed and from which a lattice parameter a_{6D} can be derived and is equal to 0.6451 nm in this case. Note the two length scale at play 1 and τ , where τ is the golden mean and which are characteristic of the icosahedral quasicrystal. These two length scales have a ratio that is irrational. There is also along this particular twofold axis an inflation property that is characteristic of the quasicrystalline long range order: if a reflexion is found at a position 1, there will be also reflexions at any power of τ , as illustrated by the red lines.

Within this scheme of superspace crystallography, the route from diffraction data to the atomic structure is in some sense similar to what is achieved in standard crystallography: the point group and space group of the quasicrystal is determined from the

Fig. 3 Illustration of the 2-D description of a 1-D quasicrystal, here the Fibonacci chain (see text).

Fig. 4 Illustration of the super-space crystallography principle (see text) in the case of the 1D Fibonacci quasicrystal. Starting from 2D lattice with segment lines as 'decoration' in direct space, its Fourier transform gives the 2D diffraction pattern. It can be indexed by two integer indices. The 1D diffraction pattern is obtained from a projection of the 2D diffraction. For the direct space the 1D structure is obtained as a section of the 2D periodic space.

Fig. 5 X-ray diffraction pattern taken along a fivefold axis in the *i*-AlPdMn phase. The two number indices is a short-hand notation for the six indices scheme. Note that the position of the indexed Bragg reflections scales with τ , the golden mean.

diffraction spectrum (see Fig. 3). Then reciprocal space data phasing allows in general to specify approximately the position and shape of the atomic surface, from this a model is proposed which is then compared to available diffraction data. We will follow these steps in the following, but first we give a brief outline of the high degree of structural quality obtained in quasicrystals.

Structural quality of quasicrystal

As for any materials, quasicrystals contain defects (vacancies, dislocations, strain, etc.), which will result in either a Bragg peak broadening or diffuse scattering. Because of the quasiperiodic arrangement, the effect of defects on the diffraction will depend on both the parallel and the perpendicular component of the reciprocal lattice vector. In the theory of QC, a distortion or a fluctuation associated with the perpendicular component has been named phason (we will come back later on this notion) and leads to changes in the diffraction pattern associated with the perpendicular component of the scattering wave-vector (Q_{per}). For instance, we can imagine that the slope of the parallel space in Fig. 3 is changing: if the slope becomes rational this will lead to a periodic structure. Such a change is equivalent to a shear strain in the perpendicular direction and has been named 'phason strain'. A distribution of phason strain will result in a broadening of the Bragg reflection (which are no longer delta peaks), in very much the same way that a distribution of elastic strain in a periodic crystal leads to a Bragg peak broadening. In the early days of quasicrystal studies, most of the obtained quasicrystals displayed distorted diffraction patterns, or Bragg peak broadening, so that the notion of long-range quasiperiodic order had been even questioned. Quasicrystals obtained most recently display a high degree of quasiperiodic long-range order, demonstrated by Bragg peaks which are almost resolution limited.

In some cases, the structural quality is such that dynamical X-ray diffraction has been evidenced. The Fig. 6 shows 2-D images of Bragg peaks obtained in a high-resolution setting. The left part shows Bragg peaks in an i-AlPdMn sample obtained by the Czochralski method, whereas the right part correspond to the same Bragg reflections, once the single quasicrystal has been annealed (Letoublon et al., 2001). As it is evident, Bragg reflections are almost resolution limited after annealing of the sample, with a coherent length which is of the order 10 μm . Of course, quasicrystals still contain some defects and are not as 'perfect' as silicon for instance, but their quality is comparable to the best inter-metallic alloys and the notion of long-range quasiperiodic order is now strongly supported by experimental results.

Fig. 6 2-D images of the Bragg reflections obtained in the i-AlPdMn phase for an as grown single grain quasicrystal (left) and the same sample after annealing (right). Whereas Bragg reflections are broadened (with a broadening proportional to Q_{per}) in the as cast sample, they are almost resolution limited in the annealed sample. From Letoublon A, Yakhov F, Livet F, Bley F, de Boissieu M, Mancini L, Caudron R, Vettier C and Gastaldi J (2001) Coherent X-ray diffraction and phason fluctuations in quasicrystals. *Europhysics Letters* **54**: 753–759.

From diffraction data to a quasicrystal model: The case of the CdYb icosahedral quasicrystalline phase

General structure determination principles and periodic approximant

The understanding of the atomic structure of quasicrystals made tremendous progresses in recent years. It can be said that in a few systems the understanding of the quasicrystal atomic structure together with its crystal chemistry is analogous to what is achieved for periodic intermetallic with relatively large unit cells. This means that not only the atomic positions have been determined, but also and very importantly the chemical nature of each atom and the way it is connected to other chemical species is well understood.

The general method used for the structure determination of quasicrystals will be exemplified with the case of the icosahedral $\text{Cd}_{5.7}\text{Yb}$ quasicrystal known as a 'Tsai' type quasicrystal, in the recognition of professor An-Pang Tsai's (1958–2019) exceptional series of new intermetallic quasicrystal discoveries (Tsai et al., 2000). The i-CdYb quasicrystal discovery is particularly interesting because this was the first binary quasicrystal, that could be obtained by slow cooling from the melt as large single grain quasicrystal. Moreover, there is a very good 'contrast' between the Cd with $Z = 48$ electrons and the Yb with $Z = 70$ electrons when X-ray diffraction is used. This means that Cd and Yb atoms can be easily distinguished by X-ray diffraction.

Finally in the same system and for a small composition change, it is possible to synthesize periodic approximants. In the high dimensional picture, a crystalline approximant can be obtained by changing the slope of the cut space which becomes rational. For instance, in the case of the 2D Fibonacci chain description if τ the golden mean is replaced by $1/1$ the resulting sequence will be LSLSLS. ... We say that in this case a $1/1$ approximant has been generated. Depending on the symmetry of the periodic approximant, there is a relation between the unit cell of the 6D periodic structure and the cell parameter of the crystalline approximant. In the case of the CdYb system a $1/1$ and $2/1$ periodic approximant can be synthesized. The Cd_6Yb phase is a cubic $1/1$ approximant with a lattice parameter equal to 1.56 nm and a $\text{Im}\bar{3}$ space group. The $\text{Cd}_{5.8}\text{Yb}$ is a cubic $2/1$ approximant with a lattice parameter τ times larger and equal to 2.52 nm (τ is the golden mean). The structure determination of these two periodic approximants gives key information for the modeling of the structure of the quasicrystal (Pay Gómez and Lidin, 2001; Pay Gómez and Lidin, 2003). Indeed, when comparing the diffraction pattern of the $1/1$ approximant and the quasicrystal, it is striking to notice that the positions of the most intense Bragg peaks are located almost (although not exactly) at the same position in reciprocal space. This is exemplified in the Fig. 7 which displays a twofold section of the reciprocal lattice of the $1/1$ approximant and the quasicrystal, the Bragg peak intensity being proportional to the area of each circle.

The main cluster which is used for the structure description of the $1/1$ and $2/1$ approximant and the quasicrystal is shown in Fig. 8. It is a series of atomic shells with an overall icosahedral symmetry except for the first shell. The first shell is a Cd tetrahedron, that occurs in several orientations and is thus disordered. The second shell is a Cd dodecahedron, the third shell is a Yb icosahedron, the fourth shell is a Cd icosidodecahedron and finally the last shell is a large triacontahedron containing 156 atoms. It is important to stress that this cluster is markedly different from what is encountered in organic chemistry with, for instance, fullerenes. Here the Cd–Yb system is an intermetallic system, with an almost close packing of a small (Cd) and a large (Yb) atom as is exemplified in the bottom row of the Fig. 8. This is very much like the case of Frank-Kasper phases. The large cluster is connected along twofold axis, sharing a face, and along threefold axis where there is an overlap as exemplified in Fig. 9. Moreover, in the $2/1$ approximant an extra 'building block' is necessary to describe the structure: a prolate rhombohedra with Cd atoms on vertices and mid-edges, together with Yb atoms along the long diagonal. All the different units that constitute the necessary 'ingredients' for the icosahedral quasicrystal modeling are displayed in Fig. 9.

Phasing the data

Solving the atomic structure of the icosahedral i-CdYb quasicrystal was achieved thanks to a large data collection of Bragg peak intensities using synchrotron radiation and a sophisticated modeling achieved in the 6-D periodic space (Takakura et al., 2007).

Fig. 7 Comparison of the twofold section of reciprocal space for the Cd_6Yb $1/1$ approximant (left) and the $\text{Cd}_{5.7}\text{Yb}$ icosahedral quasicrystal (right). The area of the disks are proportional to the Bragg peak intensities. The intensity distribution of the strongest Bragg peaks is similar. This is a signature of similar local environments.

Fig. 8 The principal cluster which can be used for the description of both the 1/1 and 2/1 approximant and the icosahedral quasicrystal in the CdYb system. Gray spheres stand for Cd atoms. Blue (respectively red) spheres stand for Yb atoms. The upper row describes the successive shells starting from a Cd disordered tetrahedron, a Cd dodecahedron, an Yb icosahedron, a Cd icosidodecahedron and a final Cd triacontahedron that contains 156 atoms. The 1/1 approximant is a BCC packing of this large cluster, which interpenetrates along the threefold axis. The bottom row is the same description in sphere packing model that emphasizes that the cluster is a close-packing of a large (Yb) and a small (Cd) atom, quite similarly to so called Franck and Kasper phases.

Fig. 9 Description of the cubic 1/1 and 2/1 approximant using the three elementary building blocks: a large triacontahedron, a prolate and oblate rhombus shown on the bottom part of the figure. The 1/1 approximant is shown on the left, the 2/1 on the central panel. The right panel shows the connection of the large triacontahedron along a twofold (b) or threefold (c) axis. From Takakura H, Gomez CP, Yamamoto A, de Boissieu M and Tsai AP (2007) Atomic structure of the binary icosahedral Yb-Cd quasicrystal. *Nature Materials* **6**: 58–63.

More than 5000 independent integrated Bragg peak intensities have been measured, from which the structure factor moduli can be extracted (square root of the Bragg peak intensities). The first step in the structure determination is to provide a first density map. As for a periodic crystal, one major problem is the so-called phase problem, since only the amplitude of the Fourier components is measured by diffraction. New phasing tools such as the low-density elimination or the charge flipping methods developed for periodic crystals, have been shown to be valid for the case of aperiodic crystals including quasicrystals. This has been a major step in the field, since before only Patterson analysis was feasible. Using these new phasing methods, which provide at least 60% of correct phases, the measured structure factors can be phased and a first 6D density map computed by Fourier transform. This is a crucial step that already leads to detailed information on the structure. An example of a section of the 6-D electron density map obtained by Fourier transform of the phased amplitudes of the CdYb quasicrystal is given in Fig. 10. The section shows the 6D periodicity and is built up by a linear combination of two 6D lattice vectors with indices $[100000]$ and $[011111]$. The segment lines, elongated in the perpendicular direction, are the traces of the 3D atomic surfaces, which lie in the perpendicular space. This is completely analogous to what was presented in the introduction. As can be seen on this figure, only three different positions in the 6D cube are occupied, labeled V (for vertex), E (for mid-edge, 0.500000) and B (for body-center, $\frac{1}{2}(111,111)$). The traces have different length in perpendicular spaces: the largest one is at the B position, then at O and finally at E. This is indicating that the atomic surfaces to be considered have significantly different sizes. We can also notice that the electron density is higher on the B site, which means that this site is likely occupied by Yb atoms for they have a larger number of electrons (70) than Cd one's (48). A complete analysis of the

Fig. 10 Section of the 6D CdYb electron density obtained by Fourier transform of the phased structure factors. The section contains a fivefold axis both in physical, parallel space and in the perpendicular space. V, E and B stand for vertex, mid-edge and body-center sites respectively. The elongated density encircled in white ellipsoids, are the traces of the 3D atomic surfaces lying in the perpendicular direction. Note that the electron density is higher at the B position, indicating this site is occupied by Yb atoms.

6D Fourier map allows one determining what are the most likely clusters in the resulting 3D quasicrystalline structure. As was already anticipated, the large Tsai-type cluster is observed, with the same chemical decoration as the one observed in periodic approximant, i.e., the icosahedron is made of Yb atoms whereas the rest of the cluster is built up with Cd atoms.

Although the previous density maps already give some information on the resulting atomic structure, it is obviously necessary to go beyond if any detailed information has to be predicted. Indeed, some phases are wrongly assigned on one hand, and on the other hand the density maps suffer from severe Fourier termination effects, which leads to unreasonable short interatomic distances. Therefore, and similarly to what is done for periodic crystals, a modeling of the structure is a necessary following step, allowing a refinement against measured data. It has to be pointed out that the comparison with diffraction data remains a powerful test, especially for weak Bragg reflections which are very sensitive to the details of the atomic structure (details of the atomic surface shape for instance).

Modeling and refining the quasicrystal atomic structure

Modeling of the atomic structure of quasicrystals requires in principle an infinite number of parameters since it is an infinite structure. Although the high dimensional description simplifies the quasicrystal picture, the number of parameters remains much larger than the one which can be refined using the diffraction data. This is why a certain number of constraints or hypothesis have been proposed to restrict models within a reasonable number of parameters.

First the chemical composition and atomic density should be close to the experimental one's. Then short distances should be avoided, and finally the crystal-chemistry should be similar to what is known with periodic approximants. All those constraints are particularly important for any atomic scale simulation of physical properties of quasicrystals. Although these constraints are 'simple' they are already difficult to fulfill, but not enough to restrict fully the modeling.

A second set of hypothesis comes with the knowledge (when feasible) of the atomic structure of periodic approximants. We have already seen that for the CdYb case the 'building blocks' to be used for the modeling of the quasicrystal structure could be determined from the 1/1 and 2/1 approximant. This is validated by the first density map calculation.

Using these set of constraints and hypothesis, a model with a restricted number of parameters (about 250) can be used for comparison with experimental data. The large overlapping triacontahedron cluster is placed on the vertices of the so-called 12-fold packing quasicrystalline network proposed by C. Henley. Indeed, this icosahedral quasicrystal networks allows to place a large triacontahedron cluster on each node of this network with cluster-cluster connections along two- and threefold axis, as this is observed in the periodic approximants. The remaining gaps in between the clusters are filled with the decorated prolate. This modeling is in fact very much compatible with the initially observed electron density (Takakura et al., 2007). Finally, the atomic positions are allowed to be moved from their 'ideal' position. This parameter is sometime called a 'parallel' shift and allows the clusters to depart from their ideal position as was identified in early modeling of quasicrystals (de Boissieu et al., 1990). This is an extremely important parameter that allows describing the crystal chemistry of the quasicrystal.

Using this approach, a full 6D model could be proposed and refined against the experimental data containing 5000 independent Bragg peak intensities. The agreement between the model and the experiment is very good with an R factor of 0.09. The 6D model can then be used to understand the corresponding 3D structure.

As expected from the model many large triacontahedron clusters can be found and are connected along 2- and threefold axis. This is illustrated in the Fig. 11 which displays the cluster distribution in the resulting 3D structure. The left part shows a 3D view of the atomic structure highlighting the large triacontahedron cluster in green and the decorated prolate in blue. This prolate is sometime isolated as observed in the 2/1 approximant, but most of the time it appears grouped in portions of the so-called Bergman cluster which is illustrated on the right part. What also results from the structure is a very strong distortion of the icosahedral symmetry of the clusters. This is illustrated in the right panel of the Fig. 11 and is the result of the orientation of the central tetrahedron. This is in fact very similar to what is observed in the 1/1 approximant in the Zn—Sc systems which is isostructural. Whereas the central tetrahedron appears as disordered at high temperature, it orders below 190 K leading to a doubling of the cell

Fig. 11 Resulting 3D quasicrystalline model as obtained from a section of the 6D model. Left panel: distribution of the large triacontahedron cluster (in green) and the decorated prolate (in blue). Some clusters formed by the prolate are highlighted. In particular the large Bergman cluster whose decomposition is shown on the right of the panel. Left panel: zoom on the first shell of the cluster, the Cd dodecahedron, as obtained after the refinement. The central tetrahedron produces a significant distortion that is clearly visible on the figure. From Takakura H, Gomez CP, Yamamoto A, de Boissieu M and Tsai AP (2007) Atomic structure of the binary icosahedral Yb-Cd quasicrystal. *Nature Materials* **6**: 58–63.

Fig. 12 Hierarchical distribution of the clusters. The position of the large triacontahedron cluster is shown by colored circles. The left panel is a fivefold section whereas the right one is a 3D view. The clusters are arranged in a cluster of clusters, here an icosidodecahedron shown as a yellow disk (10 cluster in the plane) or a yellow cluster. At a larger scale this cluster of cluster also arrange in a bigger cluster, again an icosidodecahedron shown with red link. The scale change in this hierarchical packing is τ^3 , where τ is the golden mean. From Takakura H, Gomez CP, Yamamoto A, de Boissieu M and Tsai AP (2007) Atomic structure of the binary icosahedral Yb-Cd quasicrystal. *Nature Materials* **6**: 58–63.

along 110 together with a monoclinic distortion. The ordering of the central tetrahedron induces a severe departure from icosahedral symmetry of the shells (Ishimasa et al., 2007). The very same is observed in the icosahedral phase, which might seem surprising at first sight. This distortion is clearly visible on the Fig. 11 right panel. In fact, although the icosahedral symmetry of each cluster is broken, the overall icosahedral symmetry of the structure is recovered as a result of the different orientations of the cluster upon icosahedral symmetry.

Another interesting feature of the quasicrystal structure concerns its hierarchical nature. This is exemplified with the 3D triacontahedron cluster distribution. The Fig. 12 displays the spatial distribution of the triacontahedron cluster centers. The left part is a fivefold section whereas the right part is a 3D view. When looking at the central part of the left panel, one clearly observes a ring of 10 dots, i.e., an arrangement of 10 clusters. In fact, this is a ‘cluster of clusters’ whose shape is an icosidodecahedron as shown by the yellow color clusters on the right panel. At a larger scale this yellow ‘clusters of clusters’ arrange themselves in an even larger cluster as illustrated by the red connections. This ‘inflated’ large cluster is again an icosidodecahedron. The length scale change is each time τ^3 , where τ is the golden mean. This hierarchical packing goes to infinity in the ideal quasicrystal model and is a signature of the quasiperiodic long-range order.

Finally, it is also interesting to look at the projected electron density. Because there is a long-range quasiperiodic order, the projected electron density displays clear maxima, from which dense atomic planes can be defined. An illustration is given on the Fig. 13 that displays the twofold projection of the electron density of the CdYb icosahedral quasicrystal. The gray color scale

Fig. 13 Projected atomic density of the CdYb quasicrystal on a twofold plane. The gray scale indicates the scale of the density. High density points correspond to atomic column. They are arranged in relatively dense planes, highlighted by the red dashed lines, separated by two length scale in the ratio $1/\tau$.

indicates the value of the projected density, the highest value being black. First, one clearly sees black spots, which are the signature of atomic columns. Second, it is possible to define dense atomic planes, for which the density of these columns is rather high: they are highlighted by red dashed vertical line on Fig. 13. Finally, this set of dense atomic planes are quasiperiodically distributed with two characteristic length scales related by the golden mean. Already observed in the first models proposed for the i-AlPdMn quasicrystal (Boudard et al., 1992), this description is very useful to understand the faceting or the surfaces of quasicrystals.

Other examples

Icosahedral quasicrystals

It is not possible to review all the quasicrystalline structures which have been solved since the discovery of quasicrystals in 1984. After a period of exploration of the superspace crystallography, first employed for rapidly quenched sample in the icosahedral Al—Mn systems (Cahn et al., 1988a, 1988b, 1988c), various modeling strategies have been tested. The main problem, as explained in the previous chapter, being the determination of the exact shape of the so-called atomic surface. When there are no high order periodic approximants at hand, other strategies have to be defined. They were proposed for so-called Mackay type quasicrystals, for which the main cluster is believed to be a Mackay cluster as observed in i-AlCuFe and i-AlPdMn (Boudard et al., 1992; Gratias et al., 2001; Quiquandon and Gratias, 2006) but for which a complementary Bergman cluster is of importance (Gratias et al., 2001).

For intermetallic compounds, all icosahedral structure discovered so far fall in three categories: Mackay-type, Bergman-Type and Tsai-type as a reference to the main constituting atomic cluster. Again, as emphasized in the previous paragraph, those cluster have to be viewed as rather dense sphere packing and are markedly different to what is encountered in oxide or organic compounds.

The procedure described in section “From diffraction data to a quasicrystal model: The case of the CdYb icosahedral quasicrystalline phase” is now mature and has been applied to various system. The chemical disorder, with site occupancy mixing could even been solved in a few systems such as the Zn—Sc binary quasicrystal. This structure is isomorphic to the one of the CdYb quasicrystal Zn playing the role of Cd and Sc the one of Yb. However, its chemical composition indicates that some Zn/Sc disorder should occur, unlike what is observed in the Cd—Yb case. All the tools for structure determination are mature so that this kind of chemical disorder can be dealt with, in a way that is completely similar to what is achieved for complex periodic intermetallic compounds

Fig. 14 Zn—Sc icosahedral quasicrystal structure. A fivefold section of the quasicrystal model is displayed. Zn and Sc atoms are shown as blue and red spheres respectively. Positions with a mixed Zn/Sc occupation are shown as orange spheres. They are located on specific local environments. The white lines are the traces of the large tricontahedron cluster. From Yamada T, Takakura H, Euchner H, Pay Gomez C, Bosak A, Fertey P and de Boissieu M (2016) Atomic structure and phason modes of the Sc-Zn icosahedral quasicrystal. *IUCrJ* 3(4): 247–258.

(Yamada et al., 2016). An illustration of the resulting structure is given in Fig. 14: fully occupied sites (Zn or Sc) but also mixed occupied sites are highlighted on this figure illustrating the high quality of structure determination which can be achieved now.

Such a detailed understanding of the quasicrystal structure allowed detailed studies on physical properties as for instance phonons (de Boissieu et al., 2007).

Decagonal phase

The decagonal phase is a periodic stacking of quasiperiodic planes. A large number of studies have been performed on such systems. Because of the periodic axis, if viewed along the 10-fold symmetry axis, interpretation of high-resolution transmission electron microscopy images is possible. Indeed, many models have been proposed from similar images analysis. One should keep in mind however, that the observed images are projections of the structure. In the ‘simple’ decagonal phases, where the periodicity is of the order 4 Å, there are only two different atomic layers, and the interpretation is relatively easy. This is not the case however for other decagonal phases.

The direct interpretation of images is appealing, since one can directly see the structure, although atomic resolution is difficult to achieve. The first step is to find the underlying quasiperiodic lattice, in the form of a tiling (Penrose tiling or equivalent). Note that it is not obvious, a priori, that a quasicrystal can be described by a decorated tiling. Various types of tilings have been used in the d-AlNiCo, most of them being a variant of the Penrose tiling which is made of two tiles. The second step is to find a decoration for the proposed tiling. This is achieved most of the time by super-imposing the tiling on the images (Hiraga et al., 1994). Since atoms are not visible, atom positions are inferred from the known approximant phases. An image is then simulated and compared to the experimental image. One interesting modeling has been proposed with the so-called quasi-unit cell approach. Instead of using two tiles, a single atomic cluster configuration is used to map the structure: specific overlap rules are used to generate a complete covering. Fig. 15 shows the electron diffraction pattern together with the corresponding high-resolution images. The single cluster covering is superimposed on the figure, and the decoration is shown in the enlarged part. Agreement between the simulated image and the experimental one is satisfactory (Steinhardt et al., 1998).

The same procedure as the one described for the i-CdYb quasicrystal has also been used using X-ray diffraction. In the case of decagonal quasicrystals, the atomic surfaces are 2D objects. Refinement of the occupation parameters and of the parallel shift is carried out in a similar way. The resulting structure is close to the one obtained by HREM images analysis, although a description in terms of a single cluster is probably a too crude approximation (Steurer, 2004; Steurer and Deloudi, 2009).

Beyond the ideal quasicrystalline model and phason modes

The idealized description of periodic crystals is known to be an approximation. In fact very few real materials can be described as perfectly ordered structure corresponding to the ideally infinite periodic crystal. In periodic crystals, fluctuations

Fig. 15 (a) and (b) electron diffraction pattern of the AlNiCo decagonal phase. (c) Corresponding phase contrast image. The quasi-unit cell is outlined. (d) corresponding Z-contrast images. (e), (f) and (g) quasi-unit cell decoration compared to the experimental images. Courtesy of E. Abe, NIMS, Tsukuba, Japan.

(phonons, pre-translational phonon soft modes, etc.), defects and in general disorder are present with various degrees of strength. Understanding the disorder, its correlations, its influence on physical properties is thus known to be a key challenge in solid state physics and material science. This disorder most often shows up as so-called diffuse scattering which occurs near or in between the Bragg peaks which is one of the key tools to study defects.

The same is of course true for quasicrystals. However, because of the aperiodic long-range order there are new excitations named phason modes (cp. section “[Structural quality of quasicrystal](#)”). Phason modes are a consequence of the degeneracy of the free energy with respect to a translation of the cut space, in the high dimensional description of aperiodic crystals. A detailed introduction to phason is beyond the scope of this article and can be found in ([Janssen et al., 2018](#)). The main point to be emphasized is that phason fluctuations, exactly as phonon fluctuations, will give rise to diffuse scattering with a characteristic signature in the diffraction pattern: the phason diffuse scattering is located ‘beneath’ the Bragg peaks, with a $1/q^2$ decay (q is the distance from the Bragg peak position) and a shape anisotropy that is determined by only two phason elastic constants in the case of icosahedral quasicrystals ([Janssen et al., 2018](#)). Such phason diffuse scattering has been observed in all icosahedral quasicrystals even those with an extremely high degree of perfection as shown by their Bragg width resolution limited. This is in particular the case for the i-AlPdMn quasicrystal ([de Boissieu et al., 1995](#)), whose phason fluctuations become dynamics at high temperature ([Francoual et al., 2003](#)). The [Fig. 16](#) illustrates the presence of phason diffuse scattering in the case of the icosahedral ZnSc quasicrystal. The left panel of the figure displays a 2D slice of the reciprocal space as detected on a synchrotron radiation beam line using hybrid pixel detectors. A clear anisotropic distribution of diffuse scattering is observed around the Bragg peaks.

Fig. 16 Phason diffuse scattering as observed in the Zn—Sc icosahedral quasicrystal. Left panel: Reconstructed twofold section of reciprocal space as measured by X-ray synchrotron using a Zn—Sc single grain quasicrystal. Anisotropic distribution of diffuse scattering is well visible around the Bragg peaks. Right panel: simulation of the diffuse scattering using the two phason elastic constant K1 and K2. The agreement with experiment is excellent. From Yamada T, Takakura H, Euchner H, Pay Gomez C, Bosak A, Fertey P and de Boissieu M (2016) Atomic structure and phason modes of the Sc-Zn icosahedral quasicrystal. *IUCrJ* 3(4): 247–258.

This distribution of diffuse scattering is perfectly reproduced on the right panel, using only two phason elastic constants as parameters. This is a very nice illustration of the specific phason fluctuation (here most likely quenched in) occurring in most quasicrystals.

Conclusion

In conclusion the atomic structure of quasicrystals is now rather well understood. The high dimensional approach is a very powerful tool for analyzing diffraction data and a detailed analysis and modeling is now possible. The resulting structure can be analyzed in term of clusters, local environment, and dense atomic planes. The crystal chemistry can also be well understood, in a way very similar to what is achieved for complex periodic crystals. Phason fluctuations are also important to understand the disorder of quasicrystals. It is thus fair to say that the understanding of the atomic structure of quasicrystal is now very well advanced and sufficient for the purpose of detailed atomic scale simulation for the understanding of their physical properties.

Acknowledgments

This overview is dedicated to the memory of Ted Janssen and An-Pang Tsai, two major scientists in the field of aperiodic crystals, with whom I had the chance to share many results and discussions.

Abstract

Composite materials, which we define as two or more materials bonded together, have revolutionary properties compared to traditional monolithic materials. As a result, they have had dramatic effects on an increasing number of applications. We divide them into four key classes: polymer matrix, metal matrix, carbon matrix and ceramic matrix. At this time, polymer matrix composites (PMCs) are the most widely used. In this article, we examine the four classes of composites, including reinforcements, matrix materials, manufacturing process, applications, and future developments.

Key points

- What is a composite material?
- What are the four classes of composite materials?
- What are the types of reinforcement materials?
- What are the key reinforcing fibers?
- How are composites made?
- What are the key applications of composite materials?
- What are the likely future developments?

Introduction

A composite material is two or more materials bonded together (Kelly, 1994). This definition distinguishes composite materials (composites) from materials like alloys. The most important composites consist of matrices reinforced with various types of fibers, whiskers or particles. Using composites technology, it is possible to design new, multifunctional materials with unique properties and combinations of properties that cannot be obtained with any monolithic material.

Many widely used materials are composites, but not generally recognized as such. For example, what are typically called tungsten carbide cutting tools are actually composites consisting of tungsten carbide particles bound together with a cobalt matrix, rather

than monolithic tungsten carbide (Zweben, 1994, 1998). The reason for using the composite is that it has much higher fracture toughness than monolithic tungsten carbide, a brittle ceramic.

Composites are material systems. Their properties depend on those of the constituents (reinforcement and matrix), reinforcement coating, if any, and the process by which the composite is made. All of these have pronounced effects, and altering any can greatly affect properties.

The development of composites and the related design and manufacturing technologies is one of the most important advances in the history of materials. Composites are widely used, and are enabling materials in many applications. For example, Voyager, which was in effect an all-composite aircraft, was the first to fly around the world without refueling. However, we emphasize that modern composites technology is only about five decades old. In the history of materials, this is hardly the blink of an eye. However, the basic technologies required to design and manufacture reliable structures are well developed (Gdoutos, 2018; Crane, 2018; Talreja, 2018; Johnson, 2018; Zweben, 1998).

It is common to think of composite materials primarily as structural materials. However, there are numerous examples of applications for which nonmechanical properties, such as thermal, electrical, magnetic and piezoelectric, for example, are of primary interest. Important applications based on nonmechanical properties include glass-fiber-reinforced polymer printed circuit boards, magnetic-particle-reinforced polymer audio and video recording tape and ceramic-particle-reinforced polymer sensors.

Another unique characteristic of composites is that many are made with processes that have advantages over those used for monolithic materials (Pourtarsip, 2018). To cite one example, manufacturing methods for fiber-reinforced polymers allow fabrication of aircraft structures having shapes that are aerodynamically superior to those made from metals. Another illustration is magnetic-particle-reinforced polymer permanent magnets that easily can be made into complex shapes by process like injection molding.

Composites are usually categorized by the type of material used for the matrix. The primary classes are polymer matrix composites (PMCs), metal matrix composites (MMCs), intermetallic matrix composites (IMCs), ceramic matrix composites (CMCs), and carbon matrix composites (CAMCs). The last category, CAMCs, includes carbon/carbon composites (CCCs), which consist of carbon matrices reinforced with carbon fibers (Savage, 1993). At this time, PMCs are the most widely used.

We note that biological structural materials occurring in nature are typically composites. Common examples are wood, bamboo, bone, teeth, and shell. Further, use of artificial composite materials is not new. Bricks made from straw-reinforced mud were employed in biblical times. This material also has been widely used in the American Southwest for centuries, where it is known as adobe. In current terminology, it would be described as an organic-fiber-reinforced ceramic matrix composite.

As discussed earlier, there are many types of composites. This article concentrates on those that are used primarily because of their mechanical and thermal properties.

Overview of composite materials and applications

For the purposes of this article, we divide solid materials into four categories: polymers, metals, ceramics and carbon. We consider carbon to be a separate class because of its many unique forms and characteristics. There are reinforcements and matrix materials in all four categories of solids. This results in the potential for a limitless number of new material systems having unique properties that cannot be obtained with any single monolithic material. As Table 1 shows, composites consisting of all possible combinations of matrix materials and reinforcements have been produced.

For decades, CCCs were the only significant type of CAMC (Savage, 1993). However, there are now other types of composites utilizing a carbon matrix. Notable among these is silicon carbide fiber-reinforced carbon, which is being used in military aircraft gas turbine engine components (Gonczy, 2015; Ruggles-Wrenn, 2018; Steibel, 2019).

As Table 2 shows, the characteristics of the four classes of matrix materials used in composites differ radically. This is reflected in the properties of the resulting composites.

Composites are now important commercial and aerospace materials. At this time, PMCs are the most widely used (Pourtarsip, 2018). MMCs are employed in a significant and increasing number of commercial and aerospace applications, such as automobile engines, electronic packaging, cutting tools, circuit breaker contact pads, high-speed and precision machinery, and aircraft structures (Clyne, 2018). CCCs are used in high temperature, lightly loaded applications, such as aircraft brakes, rocket nozzles, glass processing equipment and heat treatment furnaces (Ruggles-Wrenn, 2018). The Space Shuttle Orbiter has CCC leading edges.

Table 1 Classes of composite materials.

<i>Matrix</i>	<i>Reinforcement</i>			
	<i>Polymer</i>	<i>Metal</i>	<i>Ceramic</i>	<i>Carbon</i>
Polymer	X	X	X	X
Metal	X	X	X	X
Ceramic	X	X	X	X
Carbon	X	X	X	X

Table 2 Properties of selected matrix materials.

Material	Class	Density (g/cm ³)	Modulus (GPa)	Tensile Strength (MPa)	Tensile Failure Strain (%)	Thermal Conductivity (W m ⁻¹ K ⁻¹)	CTE (10 ⁻⁶ K ⁻¹)
Epoxy	Polymer	1.8	3.5	70	3	0.1	60
Aluminum (6061)	Metal	2.7	69	300	10	180	23
Titanium (6Al-4 V)	Metal	4.4	105	1100	10	16	9.5
Silicon Carbide	Ceramic	2.9	520	–	< 0.1	81	4.9
Alumina	Ceramic	3.9	380	–	< 0.1	20	6.7
Glass (borosilicate)	Ceramic	2.2	63	–	<0.1	2	5
Amorphous Carbon	Carbon	1.8	20	–	< 0.1	5–90	2

Although CMCs are not as widely used as the other classes of composites at this time, there recently have been significant applications in aircraft gas turbine engines that are indicative of their potential (Ruggles-Wrenn, 2018).

Composites technology makes possible the use of an entire class of solid materials, ceramics, in applications for which monolithic versions are unsuited because of their great strength scatter and poor resistance to mechanical and thermal shock (Ruggles-Wrenn, 2018). Further, some manufacturing processes for CAMCs are well adapted to the fabrication of large, complex structures. This allows consolidation of parts, which can reduce manufacturing costs.

In addition to their excellent structural properties, composites have unique physical properties that make them of great interest for applications such as thermal management and packaging of microelectronic, optoelectronic and microelectromechanical (MEMS) devices (Zweben, 2001, 2002a, b, 2018a, b). For example, carbon fibers with thermal conductivities much greater than that of copper are now commercially available. These reinforcements are being used in polymer, metal, and carbon matrices to create composites with high thermal conductivities that are being used in applications for which thermal management is important. Discontinuous versions of these fibers are also being incorporated in thermoplastic injection molding compounds, improving their thermal conductivity by as much as two orders of magnitude or more. This greatly expands the range of products for which injection molded polymers can be used. In addition, there are an increasing number of composites reinforced with diamond particles, which impart very high thermal conductivities and low CTEs. Thermal management materials are covered in a section near the end of the article.

Composites are now used in a wide and increasing range of important commercial and aerospace applications (Clyne, 2018; Pourtarsip, 2018; Ruggles-Wrenn, 2018; Rawal et al., 1990), including

- Internal combustion engines
- Machine components
- Thermal management
- Electronic, optoelectronic and microelectromechanical system (MEMS) packaging
- Automobile, train, ship, spacecraft, launch vehicle and aircraft structures
- Aircraft and commercial gas turbine engines
- Spacecraft structures
- Mechanical components, such as brakes, drive shafts and flywheels
- Tanks and pressure vessels
- Dimensionally stable components
- Process industries equipment requiring resistance to high-temperature corrosion, oxidation and wear
- Offshore and onshore oil exploration and production
- Sports and leisure equipment
- Biomedical devices
- Prosthetics and orthotics
- Dental restoration materials
- Civil engineering structures
- Instrument structures
- Antennas

Over the years, increasing production volumes have helped to reduce material prices, increasing their attractiveness in cost-sensitive applications.

As mentioned earlier, composites technology is in its infancy. We anticipate that new and greatly improved materials are likely to emerge. We also expect that new concepts will emerge, such as “smart materials” that incorporate greater functionality, including integration of electronics, sensors, and actuators (Peijs, 2018).

Reinforcements

The main types of reinforcements used in composite materials include continuous fibers, discontinuous fibers, whiskers (elongated single crystals), particles (including flakes) and numerous forms of fibrous architectures produced by textile technology, such as fabrics and braids (Gdoutos, 2018; Ko, 1993). In addition, there is increasing interest in composites reinforced with various types of nanoparticles, such as carbon nanotubes, graphite nanoplatelets and silica (clay) nanoparticles.

As mentioned earlier, use of natural-fiber reinforcement is far from a new idea. However, in recent years there has been considerable work on composites reinforced with a variety of naturally occurring fibrous materials, including wood fiber, kenaf, hemp, flax, jute, sisal, banana leaf, China reed and rice hulls. Matrices include thermoplastic and thermoset polymers and Portland cement. A number of material systems have been used in production applications, such as construction and automobile parts.

Increasingly, designers are using hybrid composites that combine different types of reinforcements and reinforcement forms to achieve greater efficiency and reduce cost. For example, fabrics and unidirectional tapes are often used together in structural components. In addition, carbon fibers are combined with glass or aramid to improve impact resistance. Laminates combining composites and metals, such as “Glare,” which consists of layers of aluminum and glass fiber-reinforced epoxy, are being used in aircraft structures to improve fatigue resistance. There are also examples of composites reinforced with combinations of fibers and particles.

The great importance of composites and the revolutionary improvements in properties that they offer derive to a great extent from the development of synthetic fibers with unprecedented properties (Gdoutos, 2018). The key synthetic fibers are made from glass, carbon (sometimes called graphite), ceramics and high-modulus organics, such as aramids. Most fibers are produced in the form of multifilament bundles called strands or ends in their untwisted forms, and yarns when twisted. Some fibers are produced as monofilaments, which generally have much larger diameters than strand filaments. Table 3 presents typical properties of key fibers, which we discuss in the following subsections.

Fiber strength requires some discussion. Most of the key fibrous reinforcements are made of brittle ceramics or carbon. It is well known that the strengths of monolithic ceramics decrease with increasing material volume because of the increasing probability of finding strength-limiting flaws. This is called size effect. As a result of size effect, fiber strength typically decreases monotonically with increasing gage length (and diameter). Flaw sensitivity also results in considerable strength scatter at a fixed test length. Consequently, there is no single value that characterizes fiber strength. This is also true of key organic reinforcements, such as aramid fibers. Consequently, the values presented in Table 3 should be considered approximate values and are useful primarily for comparative purposes. Note that because unsupported fibers buckle under very low stresses, it is very difficult to measure their inherent compression strength, and these properties are almost never reported. Instead, composite compression strength is measured directly.

Glass fibers

Glass fibers are used primarily to reinforce polymers. The leading types of glass fibers are E-glass, high-strength (HS) glass and corrosion resistant (CR). E-glass fibers, the first major synthetic composite reinforcement, originally was developed for electrical insulation applications (that is the origin of the “E”). E-glass fibers are, by many orders of magnitude, the most widely used of all

Table 3 Properties of key reinforcing fibers.

<i>Fiber</i>	<i>Density (G/cm³)</i>	<i>Axial Modulus (GPa)</i>	<i>Axial Tensile Strength (MPa)</i>	<i>Axial CTE (10⁻⁶ K⁻¹)</i>	<i>Axial Thermal Conductivity (W m⁻¹ K⁻¹)</i>
E-glass	2.6	70	2000	5	0.9
HS glass	2.5	83	4200	4.1	0.9
Aramid	1.4	124	3200	-5.2	0.04
Boron	2.6	400	3600	4.5	—
SM carbon (PAN)	1.7	235	3200	-0.5	9
UHM carbon (PAN)	1.9	590	3800	-1	18
UHS (IM) carbon (PAN)	1.8	290	7000	-1.5	160
UHM carbon (pitch)	2.2	895	2200	-1.6	640
UHK carbon (pitch)	2.2	830	2200	-1.6	1100
SiC monofilament	3.0	400	3600	4.9	—
SiC multifilament	3.0	400	3100	—	—
Si-C-O	2.6	190	2900	3.9	1.4
Si-Ti-C-O	2.4	190	3300	3.1	—
Aluminum oxide	3.9	370	1900	7.9	—
High Density Polyethylene	0.97	172	3000	—	—
High Modulus PBO	1.58	270	5800	-6.0	—

fibrous reinforcements. The primary reasons for this are their low cost and early development compared to other fibers. Glass fibers are produced as multifilament bundles. Filament diameters range from 3 to 20 μm . Table 3 presents representative properties of E-glass and HS glass fibers.

E-glass fibers have relatively low elastic moduli compared to other reinforcements. In addition, E-glass fibers are susceptible to creep and creep (stress) rupture. HS glass is stiffer and stronger than E-glass and has better resistance to fatigue and creep.

The thermal and electrical conductivities of glass fibers are low, and glass fiber-reinforced PMCs are often used as thermal and electrical insulators. The CTE of glass fibers is also low compared to most metals.

Carbon (graphite) fibers

Carbon fibers, often called graphite fibers in the United States, are used to reinforce polymer-, metal-, ceramic-, and carbon matrices. There are dozens of commercial carbon fibers, with a wide range of strengths and moduli. As a class of reinforcements, carbon fibers are characterized by high stiffness and strength and low density and coefficient of thermal expansion (CTE). Fibers with nominal tensile moduli as high as 895 GPa and with tensile strengths of 7000 MPa are commercially available. Carbon fibers have excellent resistance to creep, stress rupture, fatigue and corrosive environments, although they oxidize at high temperatures. Some types of carbon fibers also have extremely high thermal conductivities - many times that of copper. This characteristic is of considerable interest in electronic packaging and other applications where temperature control is important. Carbon fibers are the workhorse reinforcements in high performance aerospace and commercial PMCs and some CMCs. Of course, as the name suggests, carbon fibers are also the reinforcements in carbon/carbon composites.

Most carbon fibers are highly anisotropic. Axial modulus, tension and compression strength and thermal conductivity are typically much greater than the corresponding properties in the radial direction. Carbon fibers generally have small, negative axial CTEs (which means that they get shorter when heated) and positive radial CTEs. Diameters of common reinforcing fibers, which are produced in the form of multifilament bundles, range from 4 to 10 μm . Carbon fiber stress-strain curves tend to be nonlinear. Modulus increases with increasing tensile strain and decreases with increasing compressive strain.

The three key precursor materials for carbon fibers are polyacrylonitrile (PAN), petroleum pitch and coal tar pitch. Rayon-based fibers, once the primary CCC reinforcement, are far less common in new applications. Another type of carbon fiber, referred to as "vapor grown" by their manufacturer are made by a chemical vapor deposition type of process. Some of the latter have reported axial thermal conductivities as high as $2000 \text{ W m}^{-1} \text{ K}^{-1}$, five times that of copper.

Carbon fibers made from PAN are the most widely used. There are dozens on the market. Fiber axial moduli range from about 235 GPa to 590 GPa. They generally provide composites with excellent tensile and compressive strengths, although strength properties tend to drop off as modulus increases. Fibers having nominal tensile strengths as high as 7 GPa are available. Table 3 presents properties of three types of PAN-based carbon fibers and two types of pitch-based carbon fibers. The PAN-based fibers are standard modulus (SM), ultrahigh strength (UHS) and ultrahigh modulus (UHM). SM PAN fibers are the most widely used type of carbon fiber reinforcement. They are one of the first types commercialized and tend to be the least expensive. UHS PAN carbon fibers are the strongest type of another widely used class of carbon fiber called intermediate modulus (IM), because their axial modulus falls between those of SM and UHM carbon fibers. IM fibers are also widely used in aircraft and other aerospace structural applications. PAN fibers have relatively low thermal axial and transverse thermal conductivities.

A key advantage of pitch-based fibers is that they can be produced with much higher axial moduli and thermal conductivities than those made from PAN precursors. For example, UHM pitch fibers with nominal moduli as high as 895 GPa are available. In addition, some pitch fibers, which we designate UHK, have extremely high axial thermal conductivities. For example, there are commercial UHK fibers with a nominal axial thermal conductivity of $1100 \text{ W m}^{-1} \text{ K}^{-1}$, almost three times that of copper. However, composites made from pitch-based carbon fibers generally are somewhat weaker in tension and shear, and much weaker in compression, than those using PAN-based reinforcements.

As mentioned earlier, carbon fibers display nonlinear stress-strain behavior, making the method of calculating modulus critical. Various tangent and secant definitions are used throughout the industry, contributing to the confusion in reported properties. The moduli presented in Table 3 are based on tangents to the stress-strain curves at the origin.

Boron fibers

Boron fibers primarily are used to reinforce PMCs and, to a lesser extent, MMCs. Boron fibers are produced as monofilaments (single filaments) by chemical vapor deposition of boron on a tungsten wire or carbon filament, the former being the most widely used. They have relatively large diameters (100–140 μm) compared to most other reinforcements. Table 3 presents representative properties of boron fibers having a tungsten core and diameter of 140 μm . The ratio of overall fiber diameter to that of the tungsten core influences effective fiber properties. For example, fiber specific gravity is 2.57 for 100- μm fibers and 2.49 for 140- μm fibers. Because boron fibers are more expensive than many types of carbon fibers, their use is much more restricted.

Fibers based on silicon carbide

Silicon carbide-based fibers are used primarily to reinforce metals and ceramics. There are a number of commercial fibers based on silicon carbide. One type, a monofilament, is produced by chemical vapor deposition of high purity silicon carbide on a carbon monofilament core. Some versions use a carbon-rich surface layer that serves as a reaction barrier in MMCs and CMCs.

There are a number of multifilament silicon-carbide-based fibers made by pyrolysis of polymers. Some of these contain varying amounts of silicon, carbon and oxygen, titanium, nitrogen, zirconium and hydrogen. [Table 3](#) presents properties of selected silicon-carbide-based fibers.

Fibers based on alumina

Alumina-based fibers are used primarily to reinforce metals and ceramics. As for silicon-carbide-based fibers, they have a number of different chemical formulations. The primary constituents, in addition to alumina, are boria, silica and zirconia. [Table 3](#) presents properties of high-purity alumina fibers.

Aramid fibers

Aramid, or aromatic polyamide fibers are high modulus organic reinforcements primarily used in PMCs and for ballistic protection. There are a number of commercial aramid fibers produced by several manufacturers. As for other reinforcements, they are proprietary materials with differing properties. [Table 3](#) presents properties of one widely used aramid fiber, “Kevlar” 49. As for carbon fibers, aramid fibers have nonlinear stress-strain curves.

High-density polyethylene fibers

High-density polyethylene fibers primarily are used to reinforce polymers and for ballistic protection. [Table 3](#) presents properties of one type. The properties of high-density polyethylene tend to decrease significantly with increasing temperature, and they are susceptible to creep deformation (time-dependent deformation under constant stress), even at low temperatures.

PBO fibers

Many polymeric fibers have been developed over the years. One that appears to be making successful inroads is poly(p-phenylenebenzobisoxazole (PBO). There are two version, regular and high modulus (HM). [Table 3](#) presents properties of the latter, which has the highest modulus of any commercial organic fiber.

Applications include aerospace components, sports equipment and audio speaker cones.

Characteristics and properties of composite materials

Composites are strongly heterogeneous materials. That is, the properties of a composite material vary considerably from point to point in the material. For example, the properties of a point located in the matrix are typically very different from one in the reinforcement phase. Most monolithic polymers, ceramics, metallic alloys, and intermetallic compounds are usually considered homogeneous materials, to a first approximation. The analytical theories that define the relationships between the properties of the constituent materials making up the composite and the properties of the resulting composite are called micromechanics ([Gdoutos, 2018](#)).

Many artificial composites, especially those reinforced with fibers, are anisotropic, which means that their properties vary with direction (the properties of isotropic materials are the same in every direction). They share this characteristic with a widely used natural fibrous composite, wood. As for wood, when structures made from artificial fibrous composites are required to carry load in more than one direction, they are typically used in laminated form. The laminated form of wood is known as plywood. We note that the strength properties of some metals also vary with direction. This is typically related to the manufacturing process, such as rolling. In addition, all single crystals are anisotropic.

With the exception of MMCs, composites do not display plastic behavior as monolithic metals do, which makes composites more sensitive to stress concentrations. However, the absence of plastic deformation does not mean that composites should be considered brittle materials like monolithic ceramics. The heterogeneous nature of composites results in complex failure mechanisms that impart an effective toughness. Fiber-reinforced materials have been found to produce durable, reliable structural components in countless applications. For example, PMCs have been used in production boats, electrical equipment, and solid rocket motors since the 1950s and extensively in aircraft since the early 1970s. The technology has progressed to the point where the

entire empennages (tail sections) of commercial aircraft are made of carbon/epoxy. Passenger planes under development are scheduled to have virtually all-composite structures, including wings and fuselages.

There are a large and increasing number of materials that fall in each of the four types of composites, so that generalization is difficult. However, as a class of materials, composites tend to have the following characteristics: tailorable mechanical and physical properties; high strength; high modulus; low density; low CTE; excellent resistance to fatigue, creep, creep rupture, corrosion and wear. Composites are available with tailorable thermal and electrical conductivities that range from very low to very high.

As for monolithic materials, each of the four classes of composites has its own particular attributes. For example, CMCs tend to have particularly good resistance to corrosion, oxidation, and wear, along with high temperature capability.

The outstanding mechanical properties of composite materials has been a key reason for their extensive use in structures. However, composites also have important physical properties, especially low, tailorable coefficient of thermal expansion (CTE) and high thermal conductivity, resulting in use in an increasing number of applications. Key examples are electronic packaging and thermal management, as discussed later.

Many composites, such as PMCs reinforced with carbon and aramid fibers, and silicon carbide particle-reinforced aluminum, have low CTEs, which are advantageous in applications requiring dimensional stability. Examples include spacecraft structures, instrument structures, optical benches and optoelectronic packaging. By appropriate selection of reinforcements and matrix materials, it is possible to produce composites with near-zero CTEs.

Coefficient of thermal expansion tailorability provides a way to minimize thermal stresses and distortions that often arise when dissimilar materials are joined. For example, the CTE of silicon carbide particle-reinforced aluminum depends on particle content. By varying the amount of reinforcement, it is possible to match the CTEs of a variety of key engineering materials, such as steel, titanium, and alumina (aluminum oxide). This characteristic of composites has particular value in electronic packaging, because thermal stresses can cause failure of ceramic substrates, semiconductors, and solder joints.

There are a large and increasing number of thermally conductive PMCs, MMCs, and CAMCs. One of the most important types of reinforcements for these materials is pitch fibers. As discussed earlier, PAN-based fibers have relatively low thermal conductivities. However, pitch-based fibers with thermal conductivities more than twice that of copper are commercially available. These ultrahigh-thermal-conductivity (UHK) reinforcements also have very high stiffnesses and low densities. Fibers made by chemical vapor deposition (CVD), also called vapor-grown fibers have reported thermal conductivities as high as $2000 \text{ W m}^{-1} \text{ K}^{-1}$, about five times that of copper. Fibers made from another form of carbon, diamond, also have the potential for thermal conductivities in this range. PMCs and CCCs reinforced with UHK carbon fibers are being used in a wide range of applications, including spacecraft radiators, battery sleeves, electronic packaging and motor enclosures. MMCs reinforced with diamond particles have reported thermal conductivities as high as $1200 \text{ W m}^{-1} \text{ K}^{-1}$, three times that of copper. The latter materials are of great interest in electronic and optoelectronic packaging.

Overview of mechanical and physical properties

As discussed earlier, initially, the excellent mechanical properties of composites were the main reason for their use. However, there are an increasing number of applications for which the unique and tailorable physical properties of composites are key considerations. For example, the extremely high thermal conductivity and tailorable CTE of some composite material systems are leading to their increasing use in electronic packaging. Similarly, the extremely high stiffness, near-zero CTE, and low density of carbon fiber-reinforced polymers have made these composites the materials of choice in a variety of applications, including spacecraft structures, antennas and optomechanical system components such as telescope metering structures and optical benches.

As discussed, composites are complex, heterogeneous, and often anisotropic material systems. Their properties are affected by many variables, including in-situ constituent properties; reinforcement form, volume fraction and geometry; properties of the interphase, the region where the reinforcement and matrix are joined (also called the interface); and void content. The process by which the composite is made affects many of these variables. Composites containing the same matrix material and reinforcements, when combined by different processes, may have very different properties.

It is important to keep in mind several other important things when considering composite properties. First, most composites are proprietary material systems made by proprietary processes. There are few industry or government standards for composites and reinforcements, as there are for many structural metals. However, this limitation also applies to many monolithic ceramics and polymers, which are widely used engineering materials. Despite their inherently proprietary nature, there are some widely used composite materials made by a number of manufacturers that have similar properties. Notable examples are standard-modulus- and intermediate-modulus-carbon-fiber-reinforced epoxy.

Another critical issue is that properties are sensitive to the test methods by which they are measured, and there are many different test methods used throughout the industry. Further, test results are very sensitive to the skill of the technician performing them. As a consequence of these factors, it is very common to find significant differences in reported properties of what is nominally the same composite material. Because of these considerations, the properties of composite materials in this article should be considered approximate values. As for all materials, composite properties depend on temperature. We present room temperature values.

There is often a great deal of confusion among those unfamiliar with composites, about the effect of reinforcement form. The properties of composites are very sensitive to reinforcement form, reinforcement volume fraction and internal reinforcement geometry.

It is important to keep in mind that a key problem with discontinuous-fiber reinforcement is that it is often difficult to control fiber orientation. For example, material flow during processing can significantly align fibers in some regions. This affects all mechanical and physical properties, including modulus, strength, CTE, thermal conductivity, etc. This has been a frequent source of failures.

Traditional fabric reinforcements have fibers oriented at 0 and 90 degrees. For the sake of completeness, we note that triaxial fabrics, which have fibers at 0, +60 and -60 degrees, are now commercially available. Composites using a single layer of this type of reinforcement are approximately quasi-isotropic, which means that they have the same inplane elastic (but not strength) properties in every direction. Their thermal conductivity and CTE are also approximately isotropic in the plane of the fabric. "Perfect" fabrics would have exactly isotropic thermal properties.

Overview of manufacturing processes

Manufacturing processes for some composites have significant advantages over those used for monolithic metals and ceramics. For example, fiber-reinforced polymers and ceramics can be fabricated in large, complex shapes that would be difficult or impossible to make with other materials. The ability to fabricate complex shapes allows consolidation of parts, which reduces machining and assembly costs. For example, one-piece PMC grill opening panels are widely used in automobiles, replacing as many as 12 metal parts that have to be joined by welding or bolting.

Some processes allow fabrication of parts in their final shape (net shape) or close to their final shape (near-net shape), which also can reduce manufacturing costs. The relative ease with which smooth shapes can be made is a significant factor in the use of composites in boats, aircraft, and other applications for which fluid dynamic and aerodynamic considerations are important. We discuss manufacturing methods in the respective sections for the key composites.

Polymer matrix composites

Polymer matrix composites (PMCs) are the most efficient structural materials that have ever been developed for moderate temperature applications (Gdoutos, 2018; Pourtarsip, 2018; Zweben, 1998). As a result, they are now baseline materials in numerous applications, including aircraft, spacecraft, boats, solid-fuel launch vehicles, industrial equipment and sports equipment. At this time, thermosetting polymers are the key matrix materials for structural applications, but use of thermoplastics is gradually increasing.

There are now many reliable processes for making PMCs (Pourtarsip, 2018).

The high thermal conductivities of some PMCs has led to their increasing use in applications like spacecraft structures and electronic packaging components, such as printed circuit board heat sinks, heat spreaders and heat sinks used to cool microprocessors. The addition of discontinuous thermally conductive carbon fibers and ceramic particles to thermoplastics significantly increases thermal conductivity, opening the door to use of injection molded parts in an increasing number of applications, such as heat sinks and motor covers.

Polymers are relatively weak, low-stiffness, viscoelastic materials with low thermal conductivities and high coefficients of thermal expansion. In order to obtain materials with mechanical properties that are acceptable for structural applications, it is necessary to reinforce them with continuous or discontinuous fibers.

The addition of ceramic or metallic particles to polymers results in materials that have increased modulus. However, as a rule, strength typically does not increase significantly, and may actually decrease.

There are many particle-reinforced polymers used in electronic packaging, primarily because of their physical properties. For these applications, ceramic particles, such as alumina, aluminum nitride, boron nitride and even diamond are added to obtain electrically insulating materials with higher thermal conductivities and lower CTEs than those of the base polymer.

Metallic particles such as silver, copper, and aluminum are added to create materials that are both electrically and thermally conductive. These materials have replaced solders in some applications. Magnetic composites are made by incorporating ferrous or magnetic ceramic particles in various polymers.

As discussed, for a wide range of applications, composites reinforced with continuous fibers are the most efficient structural materials at low to moderate temperatures. Consequently, we focus on them. Table 4 presents room temperature mechanical properties of unidirectional polymer matrix composites reinforced with key fibers: E-glass, aramid, boron, standard modulus (SM) PAN (polyacrylonitrile) carbon, intermediate modulus (IM) PAN carbon, ultrahigh modulus (UHM) PAN carbon, ultrahigh modulus (UHM) pitch carbon and ultrahigh thermal conductivity (UHK) pitch carbon. The fiber volume fraction is 60%, a typical value.

The properties presented in Table 4 are representative of what can be obtained with a well-made PMC employing an epoxy matrix. Epoxies are widely used, provide good mechanical properties, and can be considered a reference matrix material. Properties of composites using other resins may differ from these.

The properties of PMCs, especially strengths, depend strongly on temperature. The temperature dependence of polymer properties differs considerably. This is also true for different epoxy formulations, which have various glass transition temperatures.

The properties shown in Table 4 are axial, transverse and shear moduli, Poisson's ratio, tensile and compressive strengths in the axial and transverse directions, and inplane shear strength. The Poisson's ratio presented is called the major Poisson's ratio. It is defined as the ratio of the magnitude of transverse strain divided by the magnitude of axial strain when the composite is loaded in

Table 4 Representative mechanical properties of selected unidirectional polymer matrix composites.

Nominal Fiber Volume Fraction = 60%.

the axial direction. Note that transverse moduli and strengths are much lower than corresponding axial values. Unidirectional composites share this characteristic with wood, which is stronger and stiffer along the grain than perpendicular to it.

Elastic moduli are based on tangents to the stress-strain curves at the origin. Using this definition, tensile and compressive moduli are usually very similar. However, this is not the case for moduli computed using various secants. These typically produce compression moduli that are significantly lower than tensile moduli, because the stress-strain curves are nonlinear.

As a result of the low transverse strengths of unidirectional laminates, they are rarely used in structural applications. The design engineer selects laminates with layers in several directions to meet requirements for strength, stiffness, buckling, etc. There are an infinite number of laminate geometries that can be selected. For comparative purposes, it is useful to consider quasi-isotropic laminates, which have the same elastic properties in all directions in the plane of the fibers. We note that through-thickness properties of quasi-isotropic laminates are somewhat similar to the transverse properties of unidirectional composites.

Laminates have quasi-isotropic elastic properties when they have the same percentage of layers every $180/n$ degrees, where n is greater than or equal to three. The most common quasi-isotropic laminates have layers that repeat every 60, 45, or 30 degrees. We note, however, that strength properties in the plane are not isotropic for these laminates, although they tend to become more uniform as the angle of repetition becomes smaller. Laminates have quasi-isotropic CTEs and coefficients of thermal expansion when they have the same percentage of layers in every $180/m$ degrees, where m is greater than or equal to 2. For example, laminates with equal numbers of layers at 0 degrees and 90 degrees have quasi-isotropic thermal properties.

Table 5 presents the mechanical properties of quasi-isotropic laminates having equal numbers of layers at 0, +45, -45 and 90 degrees. The elastic moduli of all quasi-isotropic laminates are the same for a given material. Note that the moduli and strengths are much lower than the axial properties of unidirectional laminates made of the same material. In many applications, laminate geometry is such that the maximum axial modulus and tensile and compressive strengths fall somewhere between axial unidirectional and quasi-isotropic values.

Table 6 presents physical properties of selected unidirectional composite materials having a typical fiber volume fraction of 60%. The densities of all of the materials are considerably lower than that of aluminum, and some are lower than that of magnesium. This reflects the low densities of both fibers and matrix materials. The low densities of most polymers give PMCs a significant advantage over most MMCs and CMC at low-to-moderate temperatures, all other things being equal.

As Table 6 shows, all of the composites have relatively low axial CTEs. This results from the combination of low fiber axial CTE, high fiber stiffness and low matrix stiffness. The CTE of most polymers is very high. Note that the axial CTEs of PMCs reinforced with aramid fibers and some carbon fibers are negative. This means that, contrary to the general behavior of most monolithic materials, they contract in the axial direction when heated.

The transverse CTEs of the composites are all positive, and their magnitudes are much larger than the magnitudes of the corresponding axial CTEs. This results from the high CTE of the matrix and a Poisson effect caused by constraint of the matrix in the axial direction and lack of constraint in the transverse direction. The transverse CTE of aramid composites is particularly high, in part, because the fibers have a relatively high positive radial CTE.

We note that PMCs also undergo dimensional changes due to moisture absorption and desorption. These changes are usually described by coefficients of moisture expansion, which are analogous to CTEs. This subject is beyond the scope of the current article.

The axial thermal conductivities of composites reinforced with glass, aramid, boron, and a number of the carbon fibers are relatively low. In fact, E-glass and aramid PMCs are often used as thermal insulators. As Table 6 shows, most PMCs have low thermal conductivities in the transverse direction, as a result of the low thermal conductivities of the matrix and the fibers in the radial direction. Through-thickness conductivities of laminates tend to be similar to the transverse thermal conductivities of unidirectional composites.

Table 7 presents the inplane thermal conductivities and CTEs of quasi-isotropic laminates made from the same materials as in Table 6. Here again, a fiber volume fraction of 60% is assumed.

Note that the CTEs of the quasi-isotropic composites are higher than the axial values of corresponding unidirectional composites. However, the CTEs of quasi-isotropic composites reinforced with aramid and carbon fibers are still very small. By appropriate selection of fiber, matrix, and fiber volume fraction, it is possible to obtain quasi-isotropic materials with CTEs very close to zero. The through-thickness CTEs of these laminates are positive and relatively large. However, this is not a significant issue for most applications. One exception is optical mirrors, for which through-thickness CTE can be an important issue.

The inplane thermal conductivity of quasi-isotropic laminates reinforced with UHM pitch carbon fibers is similar to that of aluminum alloys, while UHM pitch carbon fibers provide laminates with a conductivity over 50% higher. Both materials have densities about 35% lower than aluminum.

As mentioned earlier, through-thickness thermal conductivities of laminates tend to be similar to the transverse thermal conductivities of unidirectional composites, which are relatively low. If laminate thickness is small, this may not be a severe limitation. However, low through-thickness thermal conductivity can be a significant issue for thick laminates and for very high thermal loads. Through-thickness conductivity can be increased by addition of thermally conductive reinforcements such as discontinuous carbon fibers, ceramic particles like boron nitride or carbon nanotubes.

Fiber-reinforced thermoset PMCs are made by a wide variety of processes, many of which are highly automated, including hand lay-up, filament winding, tape placement, fiber placement, and various types of resin transfer molding.

A significant recent advance in PMC technology is the development of injection moldable carbon-fiber-reinforced thermoplastics with much higher thermal conductivities than those available in the past. Unreinforced polymers have thermal conductivities in the range of $0.2 \text{ W m}^{-1} \text{ K}^{-1}$. A number of commercially available PMCs consisting of thermoplastic matrices reinforced with

discontinuous carbon fibers have reported thermal conductivities ranging from 2 W m⁻¹ K⁻¹ to as high as 100 W m⁻¹ K⁻¹. Matrices include PPS, nylon 6, polycarbonate and liquid crystal polymers. These composites are also electrically conductive. Electrically insulating PMCs reinforced with thermally conductive discontinuous ceramic particles, such as boron nitride, have reported thermal conductivities of up to 15 W m⁻¹ K⁻¹.

Metal matrix composites

MMCs consist of metals reinforced with a variety of ceramic fibers, carbon fibers, whiskers, and particles (Zweben, 1998; Clyne, 2018). There are wide ranges of materials that fall in this category. An important example cited earlier is a material consisting of tungsten carbide particles embedded in a cobalt matrix, which is used extensively in cutting tools and dies. This composite, often referred to as a cermet, cemented carbide or simply, but incorrectly as "tungsten carbide," has much better fracture toughness than monolithic tungsten carbide, which is a brittle ceramic material.

Another interesting MMC, tungsten carbide particle-reinforced silver, is a key circuit breaker contact pad material. Here, the composite provides good electrical conductivity and much greater hardness and wear resistance than monolithic silver, which is too soft to be used in this application. Ferrous alloys reinforced with titanium carbide particles have been used for many years in numerous aerospace and commercial production applications, including dies, engine valves, and aircraft fuel pumps. Compared to the monolithic base metals, they offer better wear resistance, higher stiffness, and lower density.

MMCs are also have been used in automobile engine blocks. In one design, the cylinder walls of an aluminum engine block are reinforced with a combination of discontinuous aluminum oxide (alumina) and carbon fibers, enabling elimination of cast iron cylinder liners (Hayashi et al., 1989). MMCs also have been used in high-speed electronics manufacturing equipment and in equipment used for production of microprocessor chips, such as photolithography tables. Other applications include diesel engine pistons, aircraft structures, aircraft engine fan exit guide vanes, actuators, and automobile and train brake rotors.

One of the most important uses for MMCs is in electronic packaging and thermal management (Zweben, 2001, 2002b, 2018b). For example, silicon carbide particle-reinforced aluminum, often called Al/SiC in the electronics industry, is being used in high volume production parts such as microprocessor lids and power modules for hybrid electric vehicles. Other MMCs used in packaging are carbon fiber reinforced-aluminum, beryllium oxide (beryllia) particle-reinforced beryllium and silicon/aluminum. Here, the advantages are high stiffness, high thermal conductivity and low density and CTE. Two traditional packaging materials, copper/tungsten and copper/molybdenum, are also MMCs. The CTEs of all of these composites can be tailored by varying the ratio of the two constituents. Another major advantage of the newer composites is that they have relatively low densities.

Monolithic metallic alloys are among the most widely used structural materials. By reinforcing them with continuous fibers, discontinuous fibers, whiskers and particles, new materials are created with enhanced or modified properties, such as higher strength and stiffness, better wear resistance, lower CTE, etc. In some cases, the improvements are dramatic.

The greatest increases in strength and modulus are achieved with continuous fibers, at least in the direction parallel to the fibers, called the axial or longitudinal direction. As for PMCs, transverse properties are dominated by the properties of the matrix and interface. However, because the metal matrices are in themselves structural materials, transverse strength properties are frequently great enough to permit use of unidirectional MMCs in some structural applications. This is usually not possible for PMCs. The boron fiber-reinforced aluminum struts used on the Space Shuttle Orbiter are a good example. Other key MMCs reinforced with continuous fibers include silicon-carbide-reinforced titanium and carbon-fiber-reinforced aluminum.

The key particle-reinforced MMCs, include titanium-carbide-reinforced steel, aluminum reinforced with silicon carbide and with alumina particles, titanium-carbide-particle-reinforced titanium and titanium boride-reinforced titanium.

Aluminum reinforced with silicon carbide particles is arguably the most important of the newer types of structural MMCs. The low cost of the aluminum matrix and silicon carbide particles makes these composites of particular interest. There are wide ranges of materials falling in this category. They are made by a variety of processes. Properties depend on the type of particle, particle volume fraction, matrix alloy, and the process used to make them. Table 8 presents representative composite properties for three particle volume fractions, 25%, 55%, and 70%. Properties of common steel, aluminum and titanium alloys are shown for comparison.

We see that as particle volume fraction increases, modulus and yield strength increase, and fracture toughness, tensile ultimate strain and CTE of particle-reinforced composites decrease. Particulate reinforcement also improves elevated temperature strength properties and, perhaps surprisingly, fatigue resistance. The ability to tailor CTE by varying particle volume fraction is a key attribute of these materials.

There are a variety of processes to make silicon carbide particle-reinforced aluminum, including powder metallurgy, stir casting and pressure and pressureless infiltration. The last two, as well as remelt casting can make net shape or near-net shape parts. Fiber-reinforced MMCs are made by a variety of process, including pressure infiltration and diffusion bonding.

Carbon matrix composites

Carbon matrix composites (CAMCs) consist of a carbon matrix reinforced with any combination of fibers, whiskers, or particles (Savage, 1993; Zweben, 1998; Ruggles-Wrenn, 2018). For many years, the only significant CAMCs were carbon/carbon composites (CCCs), in which the reinforcements are discontinuous or continuous carbon fibers. In the last few years, a new proprietary carbon matrix material system was developed which has a silicon carbide fiber reinforcement. This material is now being used for engine flaps on a military aircraft engine. One of the key reported advantages of this new material is that it has a higher CTE than CCCs, reducing the tendency of protective ceramic coatings to crack. The focus of this section is on CCCs.

CCCs are used in a variety of applications, including electronic packaging, spacecraft radiator panels, rocket nozzles, reentry vehicle nose tips, the Space Shuttle Orbiter leading edges and nose cap, aircraft brakes, heat treating furnaces and glass making equipment.

As for PMCs, there are many different CCC materials having widely different mechanical and physical properties. The primary advantages of CCCs are: high strength compared to competing materials at very high temperatures, high stiffness, ablation resistance, high thermal conductivity (some systems), low CTEs, low density and absence of outgassing. In addition, CCCs are less brittle than monolithic carbon.

The primary disadvantages are: susceptibility to oxidation at temperatures above about 370C to 500C (700F to 930F), low interlaminar (through-thickness) tensile and shear strengths for materials with 2D reinforcement; microcracking at low stresses in

Table 8 Properties of silicon-carbide-particle-reinforced aluminum, aluminum, titanium and steel.

Property	Aluminum 6061-T6	Titanium 6Al-4 V	Steel 4340	Composite Particle Volume Fraction (%)		
				25	55	70
Modulus, GPa	69	113	200	114	186	265

CTE, 10^{-6} K^{-1}	23	9.5	12	16.4	10.4	6.2
Density, g/cm^3	2.77	4.43	7.76	2.88	2.96	3.00

some directions for 3D composites; and high cost of many systems. Because of the low interlaminar strength properties of CCCs, many applications, particularly those with thick walls often use three-dimensional reinforcement.

As mentioned earlier, one of the most significant limitations of CCCs is oxidation. Addition of oxidation inhibitors to the matrix and protective coatings raises the threshold substantially. In inert atmospheres, CCCs retain their properties to temperatures as high as 2400C (4300F).

The combination of high thermal conductivity and low density makes CCCs attractive candidates for thermal management and electronic packaging. In addition, CCCs have very low CTEs, leading to their use as thermal doublers with carbon fiber-reinforced PMC structures. The unique combination of properties possessed by CCCs, combined with a lack of outgassing, also makes them attractive for optical systems.

The two leading types of processes used to make CAMCs. The first is chemical vapor infiltration (CVI). CVI is a process in which gaseous chemicals are reacted or decomposed, depositing a solid material on a fibrous preform. In the case of CAMCs, hydrocarbon gases like methane and propane are broken down, and the material deposited is the carbon matrix. The second class of processes involves infiltration of a preform with polymers or pitches, which are then converted to carbon by pyrolysis (heating in an inert atmosphere). After pyrolysis, the composite is sometimes heated to high temperatures to graphitize the matrix. To minimize porosity, the process is repeated until a satisfactory density is achieved. This is called densification. Common matrix precursors are phenolic and furan resins, and pitches derived from coal tar and petroleum.

Ceramic matrix composites

As a class of materials, monolithic ceramics are characterized by high stiffness and hardness, resistance to wear, corrosion and oxidation, and high temperature operational capability. However, they also have serious deficiencies, which have severely limited their use in applications that are subjected to significant tensile stresses (Zweben, 1998; Ruggles-Wrenn, 2018).

A fundamental problem is that ceramics have very low fracture toughnesses, which makes them very sensitive to the presence of small flaws. This results in great strength scatter and poor resistance to thermal and mechanical shock. Civil engineers recognized this deficiency long ago, and do not use ceramic materials like stone and concrete to carry tensile loads. In the latter, this function has been relegated to reinforcing bars or prestressing cables made of steel or, more recently, PMCs. An important exception has been in lightly loaded structures where dispersed reinforcing fibers of asbestos, steel, glass, and carbon allow modest tensile stresses to be supported.

Ceramic matrix composites (CMCs) can be thought of as an improved form of carbon matrix composite in which the carbon matrix is replaced with ceramics that are stronger and much more resistant to oxidation. CMCs employ a variety of reinforcements including continuous fibers, discontinuous fibers, whiskers, and particles. Continuous fibers provide the best properties. There are many different types of CMCs, and they are at various stages of development. As discussed earlier, straw-reinforced mud is an ancient CMC, as is concrete, which consists of a cement matrix reinforced with stone and sand.

The key advantage of ceramic matrix composites is that, when properly designed and manufactured, they have many of the advantages of monolithic ceramics, such as much lower density than high-temperature metals, but are much more durable. That is, CMCs have higher effective fracture toughnesses, so that they are less susceptible to failure when subjected to mechanical and thermal shock. As a consequence, it is possible to consider CMCs for applications where they are subjected to moderate tensile loads. However, CMCs are the most complex of all types of composites, and CMC technology is less developed than that of PMCs, MMCs and CAMCs.

CMCs are being used in a number of commercial production applications. One of the most successful is silicon-carbide-whisker-reinforced alumina cutting tool inserts, which have greater fracture toughness, and are therefore more durable than monolithic alumina. Another application is silicon-carbide-whisker-reinforced aluminum nitride crucibles, which are used for casting molten aluminum. In this application, the key advantage of the CMC over monolithic ceramics is thermal shock resistance. Silicon-carbide particle-reinforced alumina is being used in slurry pumps because of the good durability and wear resistance of this material. In this application, the process makes it possible to fabricate reliable, complex parts that would be hard to make out of monolithic ceramics. Other potential high temperature CMC applications include coal fired power plant candle filters used for particulate removal, natural gas burner elements, and U-tubes. In addition, there are a wide variety of candidate applications including stationary gas turbine combustor liners and shrouds, abradable rim seals, reverberatory screens, particle separators, tube shields, recuperators, turbine tip shoes, pipe hangers, heat treating furnace fans, hot gas filters and natural gas burner elements.

Aerospace applications of ceramic matrix composites were limited until recently, when they have begun to make significant penetration in aircraft engines. The key CMCs are silicon carbide fiber reinforced silicon carbide (SiC/SiC) and oxide fiber reinforced oxide (Ox/Ox). SiC/SiC produced by an infiltration process is being used in turbine engine shrouds. Oxide-Oxide CMCs are being used on Mixers, Center Bodies and Engine Core Cowl.

One of the most significant earlier applications are fighter aircraft engine flaps. There are two types. Both use silicon carbide matrices. One is reinforced with carbon fibers, and the other a multifilament silicon carbide fiber. Another application is a missile diverter thruster made of carbon-fiber-reinforced silicon carbide. Again, the process used to make this part is CVI. The Space Shuttle Orbiter thermal protection system (TPS) made extensive use of tiles composed of a three-dimensional network of discontinuous oxide fibers with silicate surface layers. While there is no continuous matrix for most of the tile, the surface region is a form of CMC. In a sense, this can be considered at type of functionally graded material.

The addition of continuous fibers to a ceramic matrix can significantly change failure modes. Monolithic ceramics have linear stress-strain curves and fail catastrophically at low strain levels. However, well designed and fabricated CMCs display nonlinear stress-strain behavior with much more area under the curve, indicating that more energy is absorbed during failure, and that the material has a less catastrophic failure mode.

Reinforcements that have been used for CMCs include continuous fibers, discontinuous fibers, whiskers, and particles. Key continuous fibers used in CMCs include carbon, silicon carbide-based, alumina-based, alumina-boria-silica, quartz, and alkali-resistant glass. Steel wires are also have been used. Discontinuous CMC fibers are primarily silica-based. Silicon carbide is the key whisker reinforcement. Particulate reinforcements include silicon carbide, zirconium carbide, hafnium carbide, hafnium diboride, and zirconium diboride.

A large number of ceramics have been considered for matrix materials, including alumina, glass, glass-ceramic, mullite (aluminum silicate), cordierite (magnesium aluminosilicate), Yttrium alumina garnet (YAG), barium aluminosilicate (BAS), barium magnesium aluminosilicate (BMAS), calcium aluminosilicate (CAS), barium and strontium aluminosilicate (BSAS, or celsian), "Blackglas" (silicon oxycarbide or Si—O—C), silicon nitride, silicon carbide, silicon nitride-bonded silicon carbide, silicon carbide and silicon, hafnium carbide, tantalum carbide, zirconium carbide, hafnium diboride, zirconium diboride and molybdenum disilicide.

The most mature CMCs consist of silicon carbide matrices reinforced with silicon carbide-based fibers (SiC/SiC) and silicon carbide reinforced with carbon fibers (C/SiC).

As for other classes of composite materials, there are many processes that can be used to make CMCs. Key considerations in process selection are porosity and reactions between reinforcements, reinforcement coatings, and matrices. The most important processes for making CMCs at this time are chemical vapor infiltration, melt infiltration, preceramic polymer infiltration and pyrolysis (PIP), slurry infiltration, sol-gel, hot pressing and hot isostatic pressing. In addition, there are a number of reaction-based processes, which include reaction bonding and direct metal oxidation ("Dimox").

Thermal management materials

One of the most significant new areas for composites is in thermal management (Zweben, 2001, 2002b, 2018a, b). There are many engineering uses of these materials, but perhaps the most important is in packaging of microelectronics, optoelectronics and microelectromechanical systems (MEMS). Packaging provides support and protection to semiconductors and ceramics, which typically have low coefficients of thermal expansion (CTEs) and removes heat by conduction. The material requirements for these applications are high thermal conductivity, low CTE to minimize thermal stresses, and low density to minimize weight. Composites offer advantages in all three areas.

Table 9 presents properties of traditional packaging materials, including thermal conductivity, CTE, density and specific thermal conductivity, which we define as density divided by specific gravity. Specific thermal conductivity is a useful figure of merit where both thermal conductivity and weight are important. We see that, aside from CVD diamond (diamond produced by chemical vapor deposition), the maximum thermal conductivity is for copper, which has a high CTE. The materials with low CTEs all have thermal conductivities that are no better than that of aluminum. In addition, they all have relatively high densities. These are all significant deficiencies. Increasing heat fluxes has resulted in a need for improved materials.

Table 10 shows properties of some of the increasing number of new monolithic and composite packaging materials that have been developed in response to the universally recognized thermal management problems. A number are being used in production applications. Reinforcements include continuous (Cont.) and discontinuous (Disc.) thermally conductive carbon fibers, and a variety of particles, including diamond, silicon carbide and beryllia. Monolithic materials, all of which are carbonaceous, include carbon foam, natural graphite and highly oriented pyrolytic graphite (HOPG). We see that these materials offer great advantages over traditional packaging materials.

Conclusion

Composites are now baseline materials in countless applications. However, the technology, which is only several decades old, is still in its infancy. In the future, we are likely to see significant improvements in properties of existing fibers, matrices and processes, and development of new ones. So far, composites have been used primarily for their excellent mechanical properties, environmental resistance and durability. This is likely to continue. In addition, we foresee increasing use in applications for which non-mechanical properties, such as thermal conductivity and coefficient of thermal expansion are important. Among these are packaging of microelectronics, optoelectronics and microelectromechanical systems. These are extremely large and growing markets.

Development is under way on multifunctional and smart composites, which incorporate electronics, sensors, actuators and microprocessors. Potential applications include everything from spacecraft to cell phones.

Nanotechnology is one of the most exciting and challenging areas for composites. Polymers reinforced with low-cost silicate (clay) nanoparticles are already being used in commercial production applications. Carbon nanotubes and graphite nanoplatelets have impressive mechanical, thermal and electrical properties that make them attractive candidate reinforcements.

In addition to these trends, it is likely that important new materials and applications will emerge.

Abstract

This chapter provides a review of self-organization of pores in semiconductor compounds when subjected to electrochemical etching. The influence of key factors upon self-organization is elucidated under anodization of semiconductor compounds at high applied potentials or current densities implying growth of current line-oriented pores. A comparative analysis of the morphologies of pores in III-V and II-VI compounds is performed. It is shown that the direction of pore propagation can be efficiently controlled using photolithographic masks deposited prior the anodization. Besides, the formation of quasi-ordered nanotubular structures of titania via anodization of titanium foils is reviewed. The possibility for the deposition of self-organized size-saturated monolayer of metal nanodots using pulsed electroplating on porous semiconductor templates is highlighted. The prospects of application of described porous structures in light-driven micro-engines as well as in photocatalytic, photonic, electronic and ferromagnetic device structures are discussed.

Key points

- Electrochemistry as cost-effective approach for porosification of semiconductor compounds in a controlled fashion;
- Types of pores in semiconductor compounds;
- Self-ordering of pores in semiconductor compounds;
- Multilayer porous structures with modulation of the degree of porosity;
- Uniform deposition of self-assembled monolayer of metal dots via pulsed electroplating according to the proposed “hopping electrodeposition”;
- Applications of self-organized arrays of pores including those functionalized by metal.

Introduction

Starting with the rapid development of nanotechnology in the 1990s, a variety of porous materials has been reported. A considerable interest has been triggered by the discovery of macroporous Si more than three decades ago by [Lehmann and Föll \(1990\)](#). Nowadays, there are several well studied self-ordered porous materials finding applications in many fields: (i) porous alumina introduced by [Masuda and Fukuda \(1995\)](#); (ii) TiO₂ nanotubes by [Macak et al. \(2007\)](#); and (iii) self-ordered porous III-V semiconductor compounds (see the works of [Christophersen et al., 2003](#); [Föll et al., 2003a,b, 2009](#); [Langa et al., 2003](#)).

However, besides the versatility of porous alumina oxide for introducing self-ordering, its applicability is limited as a porous template to be filled in by other materials, with subsequent its removal due to the dielectric behavior leading to a passive role in the nanofabrication processes. In comparison with porous alumina, TiO₂-based nanomaterial has attracted a lot of attention in research and is considered a semiconductor nanoarchitecture with potential for a variety of applications due to its unique structural, optical and electronic properties, non-toxicity, corrosion resistance, etc. Compared to porous alumina, the templates from titanium dioxide have a number of advantages such as accessibility, biocompatibility, high photocatalytic characteristics, photostability, etc. TiO₂ nanotubes (NTs) can be fabricated via facile hydrothermal method, solvothermal method, template-mediated techniques and electrochemical anodic oxidation, the last one representing a cost-effective approach. The fabrication of TiO₂ nanotubes was

first demonstrated back in 1984 and nowadays, 4 generations of such nanostructures are known. First and second generations used aqueous solutions containing HF acid or fluorine salts and allowed fabrication of nanotubes with length up to 5 μm . However, in the latest generations, organic solutions containing fluoride salts are used which allows the fabrication of NTs up to 1000 μm long (see Paulose et al., 2007; Rani et al., 2010).

Despite the fact that TiO_2 is considered a semiconductor material, its electrical conductivity is relatively low. In connection with this, semiconductor porous structures with controlled conductivity are of major interest. Porous materials from III-V group are perfect candidates able to fill this gap. An essential contribution to the controlled nanostructuring of these materials was made by the groups of H. Föll, I. Tiginyanu, and P. Schmuki. The systematization of technological parameters, morphologies, pore geometries, etc., allowed one to elucidate the regularities of self-ordering during the pore growth (see Christophersen et al., 2003; Föll et al., 2003b, 2010). Besides the optimum electrochemical parameters (electrolyte nature and its concentration, applied anodization potential, temperature, etc.), an important factor leading to self-ordering proved to be the presence of the crystallographically oriented pores.

On the other hand, the absence of crystallographically oriented pores in II–VI semiconductors is somewhat unexpected since, for instance, ZnSe has the same zinc-blend crystal structure as GaAs, GaP and InP. This feature was explained taking into account the nature of chemical bonds between constituent atoms and electronegativity difference (Langa et al., 2011; Monaico et al., 2020a).

It is worth to mention that self-ordering in porous materials is introduced without any lithographic means. Lithographic masks are used solely to control the direction of pore growth in the restricted space under the fotorezist leading to spectacular porous architectures (Monaico et al., 2019b). Moreover, using holes in the photoresist mask leads to the formation of non-connected pore networks in a semiconductor wafer for microfluidic applications.

This chapter represents a review of the literature data and of some unpublished recent results related to self-ordering in TiO_2 nanotubular arrays as well as in III-V and II-VI porous semiconductor compounds. We present technological routes enabling one to reach self-ordering of pores aligned perpendicular or parallel to the crystal surface or even 3D modulation of the porous architecture. Along with these, promising applications of the porous materials under consideration are discussed with respect to light-driven micro-engines, photocatalytic, photonic, electronic, and ferromagnetic device structures.

Formation, morphology and physical properties of self-organized arrays of pores in semiconductor compounds

Self-organized ordered arrays of TiO_2 nanotubes

The self-organization in electrochemical technologies is a complex process that depends on many factors such as solution concentration, temperature, pH value, applied potential, etc.

An impressive hexagonal self-ordering of TiO_2 nanotubes exhibiting an increase in the internal diameter was reported by Macak et al. (2007) who studied formation of hexagonally ordered and close-packed nanotube layers by repeated anodization of Ti substrates in ethylene glycol/ NH_4F electrolytes. The authors demonstrated that among the mentioned above factors, the purity of the used Ti foil is also important for highly ordering of TiO_2 nanotubes. Besides, two step anodization similar to that used for preparing highly ordered porous alumina was applied. The nanotubes obtained during the first step were removed, and the remaining dimples served as initial sites for the formation of ordered nanotubes during the second anodization. Note that a strong variation of the nanotube wall thickness from 65 to 12 nm at the bottom and top respectively was reported. This feature was explained by chemical dissolution of TiO_2 wall in fluoride containing electrolytes.

The fabrication of TiO_2 nanotubes with V-shape profile of walls by changing the electrolyte temperature was proposed by Enachi et al. (2010b). The authors demonstrated that electrochemical etching of the Ti foil in an electrolyte containing ethylene glycol and HF allows the preparation of nanotubes with controllable inner diameter in the range from 10 nm to over 250 nm by changing the electrolyte temperature from -20°C to $+50^\circ\text{C}$. As can be seen from Fig. 1a, the electrochemical etching at applied potential of 120 V in the electrolyte containing 100 mL ethylene glycol, 10 mL H_3PO_4 and 1 mL HF at temperature 0°C leads to the fabrication of closely packed TiO_2 nanotubes with hexagonal shape. It was established that the shape of nanotubes can be changed to circular at elevated temperatures, as shown in Fig. 1b and c. An interesting peculiarity observed is that the change of the temperature leads to the increase in the inner diameter of the TiO_2 nanotubes, while the outer diameter remains unchanged, as can be seen in Fig. 1d. Based on this statement, it is possible to prepare TiO_2 nanotubes with modulated inner diameter by changing in a controlled fashion the electrolyte temperature during the electrochemical etching.

Along with this, the anodized Ti foil at low temperatures showed the initiation of a self-arranged ordered porous structure confirmed also by two-dimensional Fourier transform taken from the SEM image. The obtained porous structures demonstrated intriguing cathodoluminescence properties. Formation of resonator modes from isolated individual nanotubes as well as from cluster on TiO_2 nanotubes which are separated from each other by around 200 meV were observed from the spectral distribution of cathodoluminescence by Enachi et al. (2010a, 2012).

The obtained TiO_2 nanotubes have closed ends at the interface with the titanium foil, as a result of the formation of a barrier oxide layer. Over the time, efforts have been undertaken to develop techniques for obtaining open-ended nanotubes, which allow flow-through with increase of photocatalytic activity as well as broad applications. Albu et al. (2007) proposed and demonstrated an approach in two steps consisting of selective dissolution of titanium metal in $\text{Br}_2/\text{CH}_3\text{OH}$ electrolyte at the first step, allowing one to fabricate free-standing TiO_2 nanotubular membrane, followed by etching in HF vapors of the back side of the oxide nanotubes. Thereafter, several other approaches were reported: evaporation of Al film on Ti foil followed by anodization through Ti,

till the penetration of pores in Al due to the use of fluoride electrolyte and finally selective dissolution of Al; two-step anodization (Yip et al., 2012); double-sided anodization reported by Wong et al. (2016); applying higher anodization voltage for 5 min at the end of electrochemical etching resulting in release of free-standing membrane with open-sided TiO_2 nanotubes (Liao et al., 2012); reduction of the applied anodization voltage at the end of electrochemical etching followed by chemical dissolution of Ti foil (Kant and Losic, 2009); plasma etching using a mix of Ar and SF_6 with ratio 5:1 as reactive gas for 5 min (Ciobanu and Plesco, 2021).

Titanium dioxide can be found in three phases of crystallization: anatase, brookite and rutile. Among all the phases, the rutile phase is thermodynamically stable for titanium dioxide. The mentioned crystalline phases of titanium dioxide exhibit different properties, including density, refractive index and catalytic properties.

Enachi et al. (2009) investigated the influence of heat treatment on the structural properties of TiO_2 nanotubes by means of X-ray diffraction and Raman scattering. Raman spectrum analysis showed that the initially prepared samples are amorphous. As the annealing temperature increases to 300°C , an anatase structure is formed. After annealing at 500°C the rutile structure was observed, which coexisted with the anatase structure. Note that a complete phase transition to the rutile structure at 800°C was reported by Hummel (1984). Notwithstanding this, the performed thermal annealing in the temperature range from 450°C to 850°C for 2 h by Enachi et al. (2016), showed the presence of the peaks related to the anatase phase in the case of the sample treated at 850°C . As can be seen from Fig. 2, the maxima assigned to the rutile phase are more pronounced, but also the maxima of the anatase phase are observed which demonstrates mixed phases also for this heat treatment regime. The data are in good agreement with the review study of (Roy et al., 2011) and (Tsuchiya and Schmuki, 2020) mentioning that the complete phase transformation into rutile occurs at temperatures as high as 900°C .

The transformation process depends mainly on the structure dimensions, shape, crystallographic orientations, but also on the calcination conditions like atmosphere or calcination time (Li et al., 2016; Winardi et al., 2010; Zhao et al., 2014).

Complimentarily, the SEM and TEM analysis presented in Fig. 3 demonstrated that as-grown nanotubes possess very smooth surface without any crystal planes. However, it is clearly seen that by thermal annealing at 850°C some porosity is introduced in

nanotube walls. The detailed study of the crystallinity of the material with different phases was analyzed by Rotational Average method which calculates a medium intensity of the electron reflection at certain distance from the ED central spot (Ciobanu and Plesco, 2021). To each reflection there was assigned the corresponding crystallographic planes, which reflect the values of the lattice constant d and the intensity of the maxima. It was established that the samples treated at 450 °C show only one phase and the material is nanocrystalline, while in the samples annealed at higher temperatures all reflections can be attributed to the anatase and rutile phases, corroborating well with previously published data by Enachi et al. (2015b).

An alternative possibility to control the crystallographic structure by direct writing using a focused laser beam was proposed and demonstrated by Enachi et al. (2013). TiO₂ nanotubes with an outer diameter of about 200 nm and a wall thickness of 70–80 nm obtained by anodization in a mixture of hydrogen fluoride (1 mL) and H₃PO₄ (10 mL) in ethylene glycol (100 mL) under 100 V during 2 h were used for this purpose. The obtained samples were subjected to a thermal treatment in a nitrogen atmosphere for 30 min at temperatures between 400 °C and 900 °C in the furnace, another set of samples was heated locally with a diode pumped solid state (DPSS) laser, with a wavelength of 532 nm and a power of 7–20 mW focused on area of 20 μm². As a result of focused laser beam treatment of as-grown TiO₂ nanotubes array exhibiting amorphous phase, the anatase phase or a combination of rutile and anatase structures can be obtained in a controlled fashion. The micro-cathodoluminescence image showed a green light emission (500 nm) from the periphery of the region marked with a laser spot with a power of 13 mW, while no emission was observed inside the marking. A similar emission, but with a lower intensity, was observed at 650 nm. Besides, the panchromatic image of CL suggests that, unlike the periphery of the region marked with a laser spot, there was no emission at any wavelength inside the marked region. When the laser beam power was increased to 20 mW the CL image was different (see Fig. 4). Although the green emission comes from the periphery of the region marked with the laser spot similar to the previous case (laser beam power 13 mW), an IR emission at 800 nm is observed from inside the region marked by the laser beam (Fig. 4b), which comes from Ti³⁺ interstitial ions in the rutile phase. CL with different wavelengths emitted from different regions after laser beam marking is well illustrated in the two-color image (Fig. 4c). The Raman spectra from Fig. 4e, measured along the surface treated by the laser spot, convincingly confirms that the region of the laser spot has a rutile structure, while the periphery has an anatase structure. These results are in full agreement with the CL data. Note that transition from amorphous phase to anatase one is performed at laser beam power density lower than $0.4 \times 10^5 \text{ W cm}^{-2}$, while the rutile phase can be obtained at higher laser beam power densities. It is to be noticed that no changes in morphology were observed in samples treatment by laser beam at power density under $1 \times 10^5 \text{ W cm}^{-2}$.

Self-ordered distribution of pores in nanotemplates based on II-VI and III-V semiconductor compounds

Self-organized pores perpendicular to the crystal surface

The field of solid-state-based porous materials encompasses dielectric and semiconductor nanotemplates. Among dielectric nanotemplates, porous anodic aluminum oxide (AAO) gained interest due to the pioneer works of Martin (1994) and Masuda and Fukuda (1995). Later on, researchers (Ali et al., 2010; Ali and Maqbool, 2013) succeeded to fabricate self-organized porous

Fig. 4 Micro-CL image measured at 550 nm (a) and 800 nm (b), two-color composite image (c) and SEM image (d) taken from a TiO₂ NTs matrix treated by 20 mW power laser beam. The field of view of the image is 30.0 μm. (e) Scanning measurements of Raman spectra across a laser beam treated area and nearby regions. The laser beam with the power of 20 mW was focused on a spot with the diameter of 3 μm. Inset is the optical microscope image with the black line indicating the Raman scan. AAO via one step anodization process and to use the fabricated AAO template in nanofabrication process of highly ordered binary nanowires via electrodeposition. However, despite the high self-organization and self-ordering, AAO templates usually play a passive role in the nanofabrication due to limitations in electrical conductivity. It should be noted that the titanium oxide obtained by anodization possesses relatively low electrical conductivity. In connection with this, elaboration of conductive semiconductor nanotemplates whose properties can be adjusted by external electric fields, illumination, temperature, etc., has become an important topic of study. Good candidates suitable for nanotemplate fabrication via anodization proved to be III-V and II-VI semiconductor compounds. The versatility of morphologies and the application of porous semiconductor compounds have been described in detail in a recent review paper by [Monaico et al. \(2020a\)](#). First of all, it should be mentioned that in semiconductor compounds three types of pores were reported up to now: crystallographically oriented pores or “crysto pores”; current line-oriented pores or “curro pores”; and fractal pores. The fractal pores will not be taken into consideration in the present study due to the random distribution of pores which is far away from self-ordering and reported morphologies cannot be repeated in a controlled fashion. As it was established by [Langa et al. \(2002\)](#), the cross-sectional shape of pores, growth rate, etc., strongly depend on the applied electrochemical parameters during anodization. Moreover, the shape of nanopores can be tuned in *n*-GaP substrates with different crystallographic orientations by anodization in HBr electrolyte, as it was demonstrated by [Wloka et al. \(2005\)](#) and [Müller et al. \(2009\)](#) regarding rectangular and triangular shapes.

The authors of [Föll et al. \(2003b\)](#) focused on the formation of pores in III-V semiconductors, highlighting the main properties of the crystallographically oriented pores and current-line oriented pores. The main characteristics of the crystallographically oriented pores are the following: (i) triangular cross-sectional shape; (ii) they tend to grow along $\langle 111 \rangle_B$ crystallographic direction independent of the initial surface orientation; (iii) are obtained at low current densities; (iv) can intersect each other leading to new ultra-porous three-dimensional architectures. Among properties inherent to current line-oriented pores one can mention the following ones: (i) round cross-sectional shape; (ii) their formation requires higher applied current densities; and the last but not least (iii) they cannot intersect each other, probably the most important one from the point of view of self-ordering process.

Examples of current line-oriented pores and crystallographically oriented pores produced in an InP anodized substrate are presented in [Fig. 5a](#). It should be noted that self-organization of pores during their growth leads to hexagonal packing of pores with the formation of highly ordered templates, as can be seen in the inset from [Fig. 5a](#). The self-ordering of current line-oriented pores can be explained by the schematic illustration from [Fig. 5b](#). The process of anodization starts at some root nucleus followed by branching of crysto pores. After a certain time of anodization, usually from 10 to 20 s, when the formed nucleation layer is fully filled with pores, the branching is stopped and the second phase begins, i.e., the transition from crysto pores to curro pores occurs. Taking into account that around each pore a depletion layer (*W*) is formed and the fact that curro pores cannot intersect, they start to push each other to maintain the two depletion layers $2W$ between them. In this way, the process of self-ordering occurs without any lithographic means.

Recent systematization of the literature data demonstrated that curro pores are inherent to both III-V (except for GaAs) and II-VI semiconductor compounds, while crysto pores have been reported just in III-V semiconductor compounds (see [Monaico et al., 2020a](#)). Despite the intensive study of the GaAs material, the attempts to obtain current line-oriented pores were unsuccessful.

Fig. 5 (a) SEM image of porous InP layers anodized with changing the applied potential from 7 to 1 V resulting in formation of curro pores and crysto pores respectively. The inset represents top view of porous layer exhibiting hexagonal ordering. Schematic representation of the development of the porous structure in III-V (b) and II-VI (c) during anodic etching. (d) SEM image with experimental demonstration of the pore formation in *n*-CdSe, according to the model proposed in (c). Using n-GaAs substrates with different crystallographic orientations subjected to anodization in different electrolytes HCl, NaCl, HNO_3 , HBr, etc., showed that the crystallographic orientation influences just the direction of propagation of pores in depth, the pores being tilted to the surface for (100) and (111)A orientations; perpendicular for (111)B orientation, and preponderant parallel to the surface for (001) orientations, as is illustrated in Fig. 6. The nature of the electrolyte determines the growth speed of pores, their density, as well as the possibilities of obtaining GaAs nanowires via one step anodization in HNO_3 , as was reported by Monaico et al. (2020b, 2022b). However, some complex pores consisting of three circular pores were observed in the dynamic transitory regime of electrochemical etching during the switching of the applied voltage from a high value to a lower one or vice-versa (see Monaico et al., 2021). In spite of their circular shape, it was suggested that they are crystallographically oriented pores, round shape being explained by isotropic etching of a primary triangular pore wall formed during stationary anodization, which occurs in the subsequent dynamic regime of anodizing determined by the derivative of the current.

In contrast to III-V semiconductor compounds, the lack of crystal pores in II-VI semiconductor compounds denotes the not so high ordering of pores. In this case, the anodization starts at some imperfections at the surface and the pores grow radially away from the root nuclei, as is illustrated in Fig. 5c. During the development of the porous structure, when the condition is fulfilled that the space between two neighboring pores is bigger than 2 W, their branching takes place. The experimental demonstration of this model by Monaico et al. (2004) is presented in Fig. 5d based on anodized n-type CdSe single crystals with a concentration of free electrons of $3 \times 10^{17} \text{ cm}^{-3}$ at 300 K. When the radial porous domain meets another porous domain, the pores are forced to change their direction of propagation, and after some time of anodization, a porous network with pores parallel to each other is obtained.

Later on, using similar crystals Tiginyanu et al. (2005) showed that anodization under UV illumination results in a uniform nucleation of pore thus providing conditions for the growth of parallel pores with the diameter about 200 nm, stretching perpendicularly to the initial surface of the sample. It is worth to mention, that the width of the depletion layer strongly depends upon the concentration of free electrons and anodization voltage (see Table 1). The decrease in the thickness of pore walls down to 10–20 nm in the prepared nanotemplates based on as-grown samples with a free electron concentration of $2 \times 10^{18} \text{ cm}^{-3}$ leads to a blueshift of the excitonic emission lines by around 10 meV.

The formation of arrays of parallel pores starting with nucleation layer through radial ramification was reported in other II-VI semiconductor compounds, for instance in ZnSe (Irmer et al., 2009; Langa et al., 2011; Monaico et al., 2009b) and ZnCdS solid solutions (Colibaba et al., 2014b; Monaico et al., 2014a).

Let us discuss the issue of ZnO porosification. Due to the low chemical stability, the electrochemical nanostructuring of ZnO has been less investigated. In a recent study, Zalamai et al. (2021) reported nano-micro-nanostructuring rather than porosification. As a result of anodization, formation of nano-micro-structures with pyramidal shape on the O-face and inverted pyramids or tunnels on the Zn-face was evidenced. The applied potential during anodization allows one to tune the transverse dimensions of the produced structures. To our knowledge, up to now, porous layers with parallel pores have not been reported in the literature. Notwithstanding this, a simple technological approach of porous ZnSe matrix transformation into porous ZnO template via thermal annealing was demonstrated by Ursaki et al. (2009).

Self-organized pores parallel to the crystal surface

To make use of industrial approaches of planar semiconductor technologies, it is important to develop methods for the preparation of templates with pores oriented parallel to the top surface of the substrate. In continuation we will focus on the technological approaches of pore self-organization and technological tricks aiming at controlling the growth and direction of propagation of pores. Tiginyanu et al. (2011) demonstrated cost-effective approach for obtaining pores parallel to the InP and ZnSe crystal surface. In this study, the sample surface was covered with strips of photoresist (FR), acting as a shield against electrochemical nanostructuring of the surface underneath FR, while anodization is performed through the open windows between strips, as is illustrated in the schematic representation from Fig. 7a. According to the proposed approach, the pores start to nucleate on the surface unprotected by FR, and during the growth, the pores at the edge are forced to deflect into space under FR. The thickness of the walls of the porous

skeleton is equal to two depletion layers (2 W) due to the existence of two semiconductor-electrolyte junctions, while the thickness of the thin layer under the FR is two times smaller, implying just one semiconductor-electrolyte junction as is depicted in Fig. 7b. The experimental demonstration of the parallel pores is presented in Fig. 7c. Buried pores aligned parallel to the sample surface can be seen under the thin surface layer after the removal of the FR. Yang et al. (2017) proposed to use laser scribing process in GaN epilayers to perform lateral etching to obtain pores parallel to the top surface.

Moreover, spectacular porous architectures were obtained by applying specially designed masks on the sample surface subjected to anodization, as is illustrated in Fig. 7d. Instead of FR strips, Monaico et al. (2019b) used FL mask in the form of squares. In this case, the pores are forced to develop by the self-ordering process in the restricted space under the FR. Taking into account that the curro pores cannot intersect each other, keeping at least 2 W between them, a complicated self-organization of pores occurs. During the anodization, some pores stop to grow, while other ones are forced to change their direction of propagation in the remaining unetched space. Note that a spectacular morphology is obtained also in cross-section (see Fig. 7e). A special attention has to be paid to the left upper corner in the Fig. 7d marked with asterisk. It is clearly seen that if the corner of the used FL mask is not so sharp, the influence of the neighboring pores is not so pronounced. Taking into consideration the “competition” between pores in occupying the space under the FR, recently we investigated the evolution of self-ordering of pores through FL mask with an open window with round shape, as is illustrated in the Fig. 7f. From the SEM image after anodization of *n*-InP wafer one can see the formation of the primary pores under the photoresist and at the same time the formation of the porous domain through the open window with the formation of the secondary pores. When anodizing from the right side, the primary pores grow, avoiding the porous domain. It can certainly be concluded that anodization in combination with photolithographic means opens a new avenue for controlling the self-organization of the pores leading to new morphologies obtained by design.

Three-dimensional modulation of the porous layer

Anodization of semiconductor compounds proves to be a cost-effective tool for use in nanotechnologies due to the possibility to fabricate ordered structures such as two-dimensional (2D) single crystals of nanopores, the porous skeleton being characterized by good electrical conductivity. The results from Fig. 7 described above demonstrated that under optimum anodization conditions (at the optimum applied voltage for the formation of curro pores) the pores can be deflected to grow parallel to the crystal surface. Moreover, using FL mask with a special design, the pores grow in the restricted space under the FR, leading to a spectacular morphology due to the self-organization processes. Note, that the final morphology strongly depends on the used shape (triangle, square, octahedral shape, etc.) of the FL mask and on its transverse dimensions.

Over the last years, a considerable research activity has been focused at the fabrication of three-dimensional (3D) ordered porous structures possessing electrical conductivity. Langa et al. (2005) demonstrated formation of 3D structures by external modulation of the current density representing smooth Bragg-like structure. The anodization in 5% HCl electrolyte of (100) *n*-type InP crystals with a free carrier concentration of $3 \times 10^{18} \text{ cm}^{-3}$ was realized in galvanostatic mode at 600 mA cm^{-2} for 0.1 min in the first phase and 0 mA cm^{-2} for 0.5 min in the second phase. Our subsequent research has shown that the sequence of applied current is not very important. It was mentioned above that after beginning of anodization usually 20 s are required for the crysto pores to ramify in the so-called nucleation layer (at mentioned free electron concentration the thickness is about 2 μm) followed by self-ordering process of curro pores. An example of multilayer porous structures is presented in Fig. 8a. In the first phase, the sample was anodized in 3.5 M NaCl electrolyte at 100 mA cm^{-2} followed by anodization at consecutively changed low/high current densities ($50 \text{ mA cm}^{-2}/500 \text{ mA cm}^{-2}$) resulting in the formation of parallel porous layers with different degrees of porosity. Recent comparative study of *n*-InP anodization in HCl and NaCl electrolytes performed by Monaico et al. (2020c), revealed no significant influence of the nature of the electrolyte upon the velocity of the pore's growth.

Tiginyanu et al. (2007a) demonstrated for the first time that pulsed potentiostatic anodization (2 V, 4 V, and 6 V) of *n*-InP substrates in an environmentally friendly electrolyte based on aqueous solution of NaCl leads to spatial nanostructuring of the material through modulation of the degree of porosity and changes in the morphology of the porous layers. As illustrated in Fig. 8b, the morphology changes considerably due to the induced self-organization of pores governed by transition from crystallographically oriented to current-line oriented pores.

The absence of the crysto pores in II-VI semiconductor compounds stands out again. The formation of flat porous layers with different degrees of porosity at successive anodization in potentiostatic regime of *n*-ZnSe crystals with a free carrier concentration of $1.5 \times 10^{17} \text{ cm}^{-3}$ was reported by Monaico et al. (2007b) (see Fig. 8c). It was found that the CL emission intensity strongly depends upon the diameters of the pores which determine the thickness of the porous skeleton walls. An interesting finding was established during the successive anodization at higher voltage followed by lower applied voltage (15 V and 8 V). The morphology reported by Monaico et al. (2009b) evidenced layer porosification at different length scales as is shown in the image from Fig. 8d. This feature can be explained by the creation of thicker or thinner space-charge-region W at different applied potentials. In accordance with the Eq. (1), the space-charge-region equals

$$W = \sqrt{\frac{2 \cdot \varepsilon \cdot \varepsilon_0 (V_{bi} - V_{dc})}{q \cdot N_D}}, \quad (1)$$

where: ε —dielectric constant; ε_0 —free space permittivity; V_{bi} —built in voltage; q —elementary charge; N_D —free carrier concentration; and V_{dc} represents the applied voltage.

Experimental demonstration of the formation of a porous layer with two different diameters of pores in the same plane is presented in Fig. 8e. During the first anodization of *n*-ZnSe at 15 V a porous layer with the pore's diameter about 500 nm and thick skeleton walls is formed (see the upper porous layer in Fig. 8d). As the applied voltage is reduced to 8 V, a new porous layer is created with diameter of pores as low as 50 nm and much thinner pore walls in comparison with previous anodization (see the bottom porous layer in Fig. 8d). At the same time, these 50-nm narrow pores grow in the skeleton walls of the first porous layer. The observed successive porosification of the same layer at two different length scales opens new possibilities for the design and fabrication of device structures based on porous semiconductor compounds.

Let us pass to the issue of porosification of GaN which represents a class of wide-bandgap III-N semiconductor compounds. Almost all reported porous morphologies were obtained on GaN grown by metal organic chemical vapor deposition (MOCVD). Using light assisted wet etching, nanowires or pyramidal structures consisting of nanowires, representing threading dislocations, were reported by Youtsey et al. (1999), Díaz-Guerra et al. (2005), Radzali et al. (2014), Zhang et al. (2018), while porous layers with parallel pores obtained by anodic etching were reported in the works of Tseng et al. (2014), Kim et al. (2016), Yang et al. (2017), Li et al. (2021). It is to be noted, however, that MOCVD-grown layers suffer from internal strains and defects related to mismatches of crystal lattices and thermal expansion coefficients with the substrate, and are usually limited to thickness of 2–3 μm.

Among other growth methods, Hydride Vapor Phase Epitaxy (HVPE) has proven to be one of the most relevant techniques allowing one to obtain thick free-standing GaN substrates at growth rates up to 500 μm/h, as was reported by Bockowski et al. (2016). Applying photoelectrochemical and electrochemical etching on Ga-face and N-face of (0001) HVPE grown 300 μm thick GaN free-standing substrates acquired from SAINT-GOBAIN Crystals, Tiginyanu et al. (2016) reported three-dimensional self-organized nanostructured architectures which were assigned to spatial modulation of electrical conductivity during the HVPE growth. Fig. 9a and b illustrate the atomic force microscope (AFM) images of the surface topography recorded on the as-grown HVPE GaN substrate. Well-defined circular regions are observed, which form structures similar to concentric rings.

Taking into account that electrochemical and photoelectrochemical (PEC) etching is extremely sensitive to the local doping, electrical properties of the sample along the surface were investigated using Kelvin Probe Force Microscopy (KPFM), also known as surface potential microscopy (Fig. 9c). Self-organized 3D nanostructured architectures have been revealed, including quasi-ordered concentric hexagonal structures on both Ga-face and N-face, as shown in Fig. 9d and e. Note that KPFM is able to investigate just the sample surface, while anodization allows to study the uniformity of doping along the depth. A detailed investigation of the

modulation of electrical conductivity and lattice distortions in the as-grown and PEC etched HVPE GaN substrates was realized by Wolff et al. (2019).

According to the proposed model for the growth of bulk HVPE-grown GaN (see Tiginyanu et al., 2016) based on the obtained results and literature data, the growth process of bulk GaN via HVPE techniques is governed by the formation and subsequent overgrowth of the so-called V-type defects or pits on the film surface, as is illustrated in the schematic overview in Fig. 9f. It is expected, that on Ga-face representing growth surface, the V-type defects will be not definitely but in the huge part annihilated. Later on, different porous morphologies produced by anodization in the depth of a 300 μm thick HVPE-grown GaN substrates (MTI-corporation, USA) with respect to the N- or Ga-face were reported by Monaioco et al. (2019a). On the N-face a porous structure in the form of pyramids was formed, while homogenous porous matrices with pores oriented perpendicular to the wafer surface were generated at a depth of up to 50 μm at the Ga-face.

Hopping electrodeposition: The deposition of self-organized monolayer of Au nanodots on porous structures

Electrochemical deposition of metal nanodots has been proven to be one of the most cost-efficient and effective methods, especially when deposition is carried out on semiconductor substrates or matrices possessing electrical conductivity. Using pulsed electroplating, (Sato et al., 1999) demonstrated self-organized deposition of Pt dots on bulk n-GaAs and n-InP substrates with free electron concentration about 10^{16} cm^{-3} , while control of the dots positioning was realized by electroplating in combination with electron beam lithography. Later on, Hasegawa and Sato (2005) found the Fermi-level pinning at the metal-semiconductor interface to be greatly reduced, resulting in a strong dependency of the Schottky barrier height on the metal work function.

The possibility to cover a huge surface inherent to porous n-GaP and n-InP with free electron concentration of 2×10^{17} and $1.3 \times 10^{18} \text{ cm}^{-3}$, respectively, by a self-assembled monolayer of gold nanodots (see Fig. 10a and b) was in premiere reported by Tiginyanu et al. (2015a). Using pulsed electrochemical deposition, the authors found that after nucleation each dot increases in size up to a critical transverse dimension of about 20 nm, the process of electrodeposition of gold being continuously supported by the

Fig. 10 SEM images taken from fragments of porous GaP after electrochemical deposition of Au dots for 5 s (a) and 100 s (b). Schematic illustration of the "hopping electrodeposition" mechanism is presented in (c). formation of new nanodots. Schematic illustration of the “hopping electrodeposition” mechanism is depicted in Fig. 10c. To explain the new findings, the authors took into account the emergence of a Schottky barrier at the metal-semiconductor interface as soon as the transverse dimension of the dot reaches the threshold value. Note that the barrier potential is oriented in the opposite direction relative to the applied cathodic voltage. Under these conditions, one can imagine electrodeposition as a hopping process: gold deposition jumps to other local areas as soon as one or more dots reach the threshold value of the diameter. The process of hopping electrodeposition continues until the entire surface inherent to the porous template is covered by a monolayer of gold nanodots. It is interesting to note that after the self-assembled monolayer is formed, further electroplating of gold is spatially non-uniform and leads to the deposition of particles with relatively large diameters.

The hopping electrodeposition via pulsed electrochemical deposition of metal nanodots proved to be an original approach and effective tool for estimation of the electrical conductivity in 1D and 2D nanostructures as was demonstrated by [Monaico et al. \(2017\)](#). It is known that a good electrical conductivity of semiconductor surfaces is required for electrochemical deposition. It has been mentioned above that the electrical conductivity of the walls of the porous semiconductor skeleton is higher compared to that of the walls of porous TiO₂ or dielectric nanotemplates (like porous alumina), which ensures good conditions for the deposition of nanotubes on the inner surface of the pores. Another proof of a good electrical conductivity demonstrated by [Tiginyanu et al. \(2012\)](#) is the uniform deposition of Pt on the surface of the pores, regardless of their shape (such as, for example, circular and triangular-shaped pores).

The essence of the proposed approach for the estimation of the conductivity of semiconductor nanostructures according to their transversal geometric dimensions is the mechanism of “hopping electrodeposition” discussed above. Fig. 10d shows the SEM image of an n-InP nanowire and several nanobelts on a massive InP substrate obtained by “fast electrochemical etching” (the term introduced by [Monaico et al. \(2014b\)](#)), followed by pulsed electrochemical deposition of Au for 120 s. It is clearly seen that the surface of the nanowire, after the electrochemical deposition of Au, is covered by a uniform monolayer of gold nanodots and some larger gold conglomerates at higher magnification in Fig. 10e. Several larger Au conglomerates are formed because the deposition time is longer than the time required to deposit a monolayer of 20 nm size-saturated Au dots. Unlike nanowires, the surface of nanobelts remains intact, meaning that no electrochemical deposition occurs on them.

As concern 10 nm thick n-InP nanowalls, possessing an intermediate thickness between nanowires and nanobelts, a comparative Au electroplating is presented in Fig. 10f. It should be mentioned that all nanostructures (nanowires, nanobelts and nanowalls) are produced simultaneously at the same bulk n-InP substrate, and the electroplating is performed on them in the same process. Comparing Au deposition on nanowires (SEM images in Fig. 10e and f), it can be stated that few larger Au nanoparticles are deposited on the monolayer of Au nanodots within 120 s (Fig. 10e), while the number of large nanoparticles deposited on nanowires increases significantly after deposition for 300 s (Fig. 10f). Also, in Fig. 10e it can be seen that the density of large Au nanoparticles on nanowires and on the massive InP substrate is almost the same, which suggests that the electrical conductivity of nanowires is comparable to that of massive semiconductor crystals. In contrast, the surface of the nanowall in Fig. 10f is only partially covered by Au nanodots, which means that 20 nm Au nanodots monolayer is not completely formed on the surface of the nanowall. One can conclude that the nanowall has an intermediate conductivity value between those of the nanowire and the nanobelt.

Nowadays, metal nanostructures play an important role in many applications, for instance in nanoelectronics, plasmonics and nanophotonics. Traditionally, metal nanoparticles are obtained in solutions, and positioning them on a chip remains a challenge.

A method for controlled deposition of metallic nanodots along predetermined directions by using cost-effective and accessible techniques was proposed and demonstrated by [Monaico et al. \(2019b\)](#). The proposed approach can be explained by Fig. 7a and b. During the anodization using FL-based process, a thin surface layer with the thickness of one SCR is formed under the FL mask, in contrast to the thickness of the porous skeleton walls. Taking into consideration that the electrochemical deposition occurs selectively on semiconductor nanostructures, depending on their geometric parameters, especially thickness, the electrodeposition takes place along the walls of the first row of pores (having thickness 2 W) under this thin layer (with the thickness 1 W).

The mechanism of hopping electrodeposition was used for the fabrication of free-standing large-area nanoporous gold membranes in the work of [Monaico et al. \(2020d\)](#). In this approach, at the beginning a thin film consisting of gold nanodots is deposited on GaAs surface, the perforation of this layer being controlled by the width of the deposition pulse. The procedure is followed by electrochemical etching of GaAs substrate through deposited Au film. As was demonstrated, during the porosification of GaAs, the reaction gases contribute to the detachment of the Au layer, resulting in free-standing perforated Au membrane that can be transferred to other substrates, inclusive flexible ones due to the excellent flexibility of the membrane.

The modulation of the electrical conductivity of GaN crystals during the HVPE growth was also highlighted by the study of the electrochemical deposition of gold governed by the mechanism of “hopping electrodeposition.” During the electrochemical deposition of Au, as in the case of electrochemical etching, the current passes through the electrical path with the lowest resistance. Thus, experimentally optimizing the parameters of electrochemical deposition, especially the value of the amplitude of the deposition pulse, predominant deposition of gold on regions with higher conductivity was realized, forming concentric structures similar to those in Fig. 11b. It should be noted that regions with different conductivities can also be identified with the help of an electron microscope, by evidencing different contrast in SEM images, as is presented in Fig. 11a.

Thus, the combination of electrochemical nanostructuring of semiconductor substrates and electrochemical deposition of metals is a powerful tool for the manufacture of new hybrid metal-semiconductor nanoarchitectures for various electronic, photonic and plasmonic applications.

Fig. 11 (a) SEM image of the as-grown HVPE GaN substrate with back-scattered electron detector (BSE). (b) SEM image with secondary electron detector (SE) of the sample from (a) after pulsed electrochemical deposition demonstrating gold deposition on regions with higher conductivity forming concentric structures.

Applications of self-organized ordered arrays

At present, low-dimensional materials are in the attention of both scientists and manufacturers of electronic and photonic devices. The widespread implementation of nanometer-sized devices has already revolutionized information and communication technologies, and is currently working intensively in various fields vital to civilization, such as medicine, the environment, renewable energy sources, etc. The most enigmatic phenomena are hidden in the labyrinth of nano-object interactions. In this context, in continuation we will focus on some applications of elaborated and described above nanostructures: micro-submarines consisting of networks of TiO_2 nanotubes with capabilities to transport micro- and nano-capsules in a fluid environment, photonic and photocatalytic applications as well as a micro-nano-device with a record capacitance per square micrometer based on self-organized porous GaP/Pt nanocomposites. It is worth to mention also the perspective for using self-organized porous architectures for nonlinear optical applications (see the works of Reid et al., 2005a,b; Radhanpura et al., 2010), although we will not address this issue here.

a. Light-driven micromotors

The term “nanobots” attracted attention after the famous essay given by the Nobel laureate Prof. Richard Feynman in 1959 and published later in 1992 (Feynman, 1992), mentioning the potential to “swallow the surgeon” of machines small enough for us to ingest. Nowadays, researchers intensively work on creation of micro-nano-robots, able to transform chemical energy or the energy of the external field into motion, with the aims to perform certain complex tasks, for instance drug-delivery systems as it was described in review work of Medina-Sánchez et al. (2018) as well as in the Chapter by Mariana Medina-Sánchez, Microrobots. In general, micromotors are classified according to the energy source for the propulsion of the micromotor. Four sources of energy are known to propel the micromotors: light; ultrasound; magnetic and electric fields (Dong et al., 2016; Leal-Estrada et al., 2021; Cao et al., 2021; Niedert et al., 2020; Rajabasadi et al., 2021).

Light is one of the most attractive fuels for micro- and nanomotors, because it is a renewable energy source that can be easily controlled, does not require physical connections to micromotors, and usually does not lead to the formation of impurities. Two major advantages should be mentioned for light-driven micromotors: the speed of the motors can be controlled by the intensity of the light and the on/off switching mechanism is fast. To date, most light-driven micro- and nanomotors use ultraviolet or visible light. Up to now different low-dimensional objects were used as self-propelled micromotors, for instance tubular structures by Wrede et al. (2021), nanowires by Karaca et al. (2021), nanoparticles by Hu et al. (2022).

It is worth mentioning that most of the studies have been focused on the development of micromotors based on individual nanostructures. A self-propelled light-driven micromotors, named by authors micro-submarines, based on TiO_2 self-organized arrays of nanotubes, with the inner cone-shaped cavity, capable to pick-up and release the micro-particles was reported by Enachi et al. (2016) (see Fig. 12). The cargo capability takes place due to the distribution of tasks in the network of nanotubes, where some nanotubes are responsible for the cargo while transportation is provided by other nanotubes under UV illumination. Propulsion is generated by the ejection, through the wide ends of the nanotubes, of the oxygen bubbles formed inside of nanotubes due to the photocatalytic properties of titanium dioxide. The first demonstration of light-controlled bubble-propelled single-component metal oxide tubular TiO_2 microengines has been realized by Mou et al. (2015). In the process of moving, the micro-submarine captures micro- or nano-particles in its path and keeps them attached to the narrow ends of some nanotubes, while other nanotubes in the network continue to work as nano-motors, thus contributing to the propulsion of the submarine. The release of taken on board micro- or nano-particles is realized by interrupting the UV light.

b. The prospect of using metallized TiO_2 nanotubes as photonic lenses

Numerical calculations using the multiple-scattering approach showed that the focusing properties of flat and concave lenses assembled from TiO_2 nanotubes with metallized inner and outer surfaces are comparable to those of lenses made of nanorods with a negative refractive index $n = -1$. Negative Index Materials (NIM) introduced by Veselago (1968) are synthetic materials that

Fig. 12 (a, b, c) Optical images and corresponding tracking of a microarray of TiO₂ nanotubes during (a) 61 s, (b) 85 s, and (c) 55 s, moving under the UV illumination (d), along with the corresponding tracking (starting point is labeled by t_0). The average speed associated with the aforementioned tracks is represented in panel (e). The power density of the UV irradiation constitutes (a) 0.02 mW cm⁻², (b) 0.15 mW cm⁻², and (c) 0.3 mW cm⁻². (f) SEM image of a cluster of titanium oxide nanotubes. Reprinted from Enachi M., Guix M., Postolache V., Ciobanu V., Fomin V.M., Schmidt O.G., Tiginyanu I. (2016) Light-induced motion of microengines based on microarrays of TiO₂ nanotubes. *Small* 12: 5497–5505. <https://doi.org/10.1002/sml.201601680>. Copyright © 2016 with permission from John Wiley and Sons.

exhibit amazing optical properties and enable one to develop new optical elements. Note that Veselago's work did not arouse the interest of researchers for a relatively long period of time. Only several decades later, due to the development of nanotechnologies and low dimensional materials, a great effort was focused at exploration of lenses with different configurations and composition capable to operate especially in the visible region of the spectrum, as it was reported by Pendry (2000); Foca et al. (2005, 2009); Sergentu et al. (2004, 2006, 2007); Tiginyanu et al. (2009); Vanb  sien and Centeno (2014); Fan et al. (2017), etc.

Sergentu et al. (2008) proposed to assemble NIM from TiO₂ nanotubes with inner and outer surfaces covered with a thin film of metal. Although both flat and concave lenses showed focusing properties, the focusing characteristics of concave lenses proved to be better. Moreover, according to the results of simulations, introducing a disorder in the arrangement of TiO₂ nanotubes contributes to the improvement of the focal spot.

The high resistivity of the TiO₂ nanotubes implies application of costly and sophisticated deposition techniques for metallization, Atomic Layer Deposition (ALD) providing uniform deposition along the whole nanotube's depth (Dvorak et al., 2019). It was mentioned above, that templates based on semiconductor compounds from III-V and II-VI groups can be easily decorated by metallic nanotubes, nanowires or nanodots via pulsed electrochemical deposition representing cost-effective technology for InP (Tiginyanu et al., 2008); GaAs (Monaico et al., 2022a,b); GaP (Tiginyanu et al., 2015b); ZnSe (Tiginyanu et al., 2011; Monaico et al., 2009b). For the development of photonic lenses working in the visible region of the spectrum, materials possessing wider bandgaps should be used, for instance GaP and ZnSe. The results of calculations demonstrated good focusing properties of flat photonic lenses assembled from metallized porous GaP slabs, especially at long wavelengths including the far infrared spectral range (see Tiginyanu et al., 2015b) as well as prospects of novel focusing elements and beam splitters based on metallized ZnSe porous structures for application in the visible region of the spectrum (Tiginyanu et al., 2011). It should be mentioned that focusing properties are determined by the morphology (geometry of nanotubes and their spatial distribution) of the structure and the material used.

c. Photocatalytic applications

Among other semiconductors, TiO₂ is considered as one of the most promising materials for photocatalytic applications due to the low-cost production, low toxicity among the possibilities to obtain a large active surface in a relatively small volume. The photocatalytic reactions on TiO₂ nanoparticles have been investigated for almost 50 years. In the last 10 years, however, the research interest was attracted by one-dimensional nanostructures, namely by the arrays TiO₂ nanotubes providing more control over morphology and charge-carrier separation mechanism. An important criterion to enhance the photocatalytic activity was found to be the crystalline phase as well as the relative percentages of anatase and rutile phases in the samples, as was reported by Zakir et al. (2022); Luo et al. (2015); Wang et al. (2020); Nie et al. (2021). According to the study of Enachi et al. (2015a), the anatase phase was found to be efficient for the photodegradation of Rhodamine B dye under UV light with enhancement of the percentage of degradation by samples doped with Ag. It should be mentioned that doping or covering with other noble metals like Au and Pt showed negative impact on photodegradation of Rhodamine B dye. On the other hand, functionalization of TiO₂ nanotube arrays with Au, Pt or Pd nanoparticles resulted in high-efficiency photocatalytic H₂ production from ethanol solutions, as was reported in the works of Lee et al. (2013); Hejazi et al. (2019); Wang et al. (2021); Yoo et al. (2018); and Kim et al. (2021). The impact of functionalization via different deposition techniques and structural engineering of TiO₂ nanotube arrays was reflected in review works of Lim et al. (2019) and Zhou et al. (2017).

Shaban et al. (2019) reported efficient photocatalytic degradation of methylene blue (MB) using Ni-doped TiO₂ nanotubes under visible light. Besides, Ciobanu and Plesco, 2021 performed a comparative study of the degradation of MB under UV or visible light using TiO₂ nanotubes annealed at different temperatures. The amount of 20 mg of TiO₂ nanotubes with crystalized anatase phase, as a result of annealing at 650 °C, demonstrated 85% photodegradation of MB under UV illumination for 25 min, while higher photocatalytic activity in the visible light demonstrated samples possessing predominant rutile phase (thermally treated at 850 °C). The anatase phase was found to be more efficient also for the degradation of acid orange, as was reported by Liu et al. (2012).

d. Variable capacitance micro-nano-device

Porous semiconductor nanotemplates due to their properties that can be engineered find wide applications in electronics, optics, biomedical applications, photonics, etc. Among advantages over other porous templates like porous anodic aluminum oxide or etched ion-track membranes one can mention the following ones: (i) the properties of semiconductor nanotemplates can be adjusted by application of external electric field, illumination, temperature, etc., and (ii) semiconductor nanotemplates possess higher electrical conductivity of porous skeleton, providing favorable conditions for metal nucleation (Tiginyanu et al., 2015a) and uniform deposition on the pores walls without any activation or sensibilization of the porous skeleton walls, avoiding contamination (Tiginyanu et al., 2008; Monaco et al., 2020a). Combining electrochemical etching and electroplating for the purpose of filling semiconductor nanotemplates with metal increases the area of their applications in nanoelectronics and optoelectronics.

In the work of Vanmaekelbergh et al. (1997) the formation of a semiconductor/metal Schottky barrier junction with a huge internal contact area is produced between interpenetrating GaP and gold nanometer-scale network systems. The huge surface of a Schottky contact implies an enormous capacitance, which has been exploited in a variable capacitance device developed by Tiginyanu et al. (2012) on two-dimensional metal-semiconductor networks prepared via pulsed electrochemical deposition of Pt on the walls of pores inside of self-organized porous GaP templates with parallel pores.

The morphology in cross-section of the developed micro-nano-device is presented in Fig. 13a. In the process of variable capacitance device elaboration, two important issues were taken into account, namely: (i) to assure the high value of the Schottky

Fig. 13 (a) The morphology of deposited Pt nanotubes in porous GaP template used for the fabrication of a variable capacitance device. (b) The consequence of pulses and the duration between the pulses allowing the deposition of frontal contact connected to all nanotubes in the same process of the Pt deposition. (c) The schematics of the device: porous GaP template (red color); deposited Pt inside porous GaP template and frontal surface acting as Schottky contact (green color); Ohmic contact deposited on backside of bulk GaP substrate (black color). (d) Current-voltage characteristics. (e) Capacitance-voltage characteristics. Panels (a, d and e): Reprinted from Tiginyanu I., Monaco E., Ursaki V. (2012) Two-dimensional metallo-semiconductor networks for electronic and photonic applications. *ECS Transactions* 41: 67–74. <https://doi.org/10.1149/1.4718392>. Copyright © 2012 The Electrochemical Society. Reproduced by permission of IOP Publishing Ltd. All rights reserved.

barrier (about 1.1–1.3 eV for Pt on GaP), and (ii) the right choice of the width of the porous skeleton walls, to assure overlapping of the two depletion regions in the skeleton walls, starting from a certain applied potential. Therefore, the width of a wall between pores cannot be less than the double depletion region without applied potential. According to the work of [Tiginyanu et al. \(2012\)](#), the thickness of the porous GaP layer was 70 μm in 500- μm thick substrate. The Schottky contact was deposited by means of pulsed electroplating of Pt on the inner surface of the porous skeleton and on the top surface by switching the duration between the pulses (t_2) from 1 s to milliseconds (see [Fig. 13b](#)). The proposed approach of electrochemical deposition of the top contact in the same technological process assures the connection of each grown Pt nanotube to the formed Pt top contact. In this case the nanotubes are spliced with the deposited layer on the surface. The ohmic contact from the backside of the sample was realized by deposition of In. The schematic representation of the variable capacitance device based on Pt/porous GaP is presented in [Fig. 13c](#).

The measured current-voltage and capacitance-voltage characteristics of the elaborated device is presented in [Fig. 13d](#) and [e](#), respectively. One can see from this characteristic that the capacitance starts to decrease sharply from 12 to 2 nF under the applied negative potential in the range from 0.5 to 4 V, indicating that the device reaches a capacitance density variation of about $6 \times 10^{-3} \text{ pF V}^{-1}$ per $1 \mu\text{m}^2$ of surface. This value is much higher in comparison with other 2D variable capacitance devices based on flat p-n junction or deposited two-dimensional thin film on the semiconductor surface. More recently, [Monaico \(2022\)](#) proposed and elaborated the technological route of pulsed electrochemical deposition in 300 μm deep porous GaP template with the aim to increase capacitance by 4–5 times. The optimization of parameters of pulsed electrochemical deposition showed that uniform deposition of Pt nanotubes inside 300- μm long pores occurs at pulse duration of 100 μs and the duration between pulses of 3 s during 15 h of electroplating.

e. Ferromagnetic core-shell coaxial GaAs/Fe nanostructures

Among noble metals, magnetic nanoparticles have been intensively studied over the last years due to their unique magnetic properties, along with other characteristics important for various applications. Moreover, apart from applications of individual magnetic nanoparticles, arrays of ferromagnetic nanostructures such as wires and tubes are of interest in the field of high-density data storage, microelectronics, spintronics, and microwave devices, as was reported by [Piroux \(2020\)](#); [Mohammed et al. \(2017\)](#); [Staño and Fruchart \(2018\)](#). According to the works of [Bran et al. \(2021\)](#); [Bran \(2022\)](#); [Streubel et al. \(2016\)](#); [Ruiz-Clavijo et al. \(2019\)](#); [Körber et al. \(2022\)](#) the possibilities to tune the geometry of the magnetic nanotubes give rise to novel effects and functionalities. In particular, tubular arrays and coaxial core-shell structures offer advantages over nanowires, owing to the possibilities to vary the thickness of the tube wall or the shell in addition to the control of the length and diameter ([García et al., 2021](#); [Proenca et al., 2020](#)).

An important peculiarity of anodization of GaAs is the absence of current line-oriented pores in this material as was discussed in section “Self-organized pores perpendicular to the crystal surface.” Thus, anodization of GaAs substrates leads to the formation of crysto pores having triangular cross-sectional shape ([Föll et al., 2003b](#)), and at optimized applied potential the transition from pores to nanowires occurs as was reported by [Li et al. \(2011\)](#); [Asoh et al. \(2014\)](#); and [Monaico et al. \(2020b\)](#). As a result of electrochemical deposition of Fe, [Monaico et al. \(2022b\)](#) reported recently the possibilities to produce magnetic nanotube arrays with triangular cross-sectional shape (see [Fig. 14a](#)) oriented both in-plane and out-of-plane with the substrate surface. The results illustrated in the inset from [Fig. 14a](#) correspond to Fe electroplating at a short time of electrodeposition to disclose the triangular shape of nanowires. An important finding is that nanowires are oriented perpendicularly to or preponderantly parallel with the GaAs surface in the case of used (111)B or (001) crystallographic orientation of GaAs wafer, respectively. It was found that the coercivity and the remanence ratio of polycrystalline Fe nanotubes deposited on GaAs nanowires increase with increasing their coverage with Fe nanoparticles. The produced structures exhibited also some magnetic anisotropy with respect to the coercivity and the remanence ratio.

Going back to the shape control of the nanostructures, it should be mentioned that based on our preliminary results, nanowires with round cross-sectional shape (see [Fig. 14b](#)) were obtained under anodization of (001) oriented GaAs substrates at applied potential between the nanowires formation and electropolishing. Further, along with pores with triangular shape and absence of crysto pores in GaAs, pores with circular shape were fabricated by [Monaico et al. \(2021\)](#) under stationary and dynamic regimes of anodization. The unusual circular shape for crysto pores was explained by isotropic etching of the walls of a primary triangular pore formed during stationary anodization, which occurs in the subsequent dynamic regime of anodization determined by the derivative of the current.

Keeping in mind the fascinating property of crysto pores to intersect each other, diameter modulated GaAs nanowires can be easily produced by cost-effective electrochemical etching techniques. According to features of galvanostatic and potentiostatic anodization of (111)B oriented GaAs substrates reported in details by [Monaico et al. \(2020b\)](#), at certain values of anodization current or voltages, a combination of crysto pores aligned perpendicularly to the sample surface and tilted pores intersecting them was evidenced. This finding enables one to fabricate nanowires with modulated diameter or perforated nanowires at optimized anodization parameters (potential, electrolyte, temperature, etc.), as illustrated in [Fig. 14c](#) and [d](#).

The impact of the shape and alignment of GaAs nanowires upon magnetic properties of core-shell GaAs/Fe nanostructures is the subject of our further investigations.

Fig. 14 Schematic representation of core-shell GaAs/Fe nanostructures with triangular (a) and circular cross-sectional shapes in (b). The inset represents SEM images of GaAs nanowires after Fe electroplating. SEM image of diameter modulated GaAs nanowires at anodization potential of 4.5 V in 1 M HNO_3 of (111)B oriented GaAs crystals for a short time, leading to self-induced oscillations in nanowires diameter, followed by anodization at 4 V resulting in smooth side walls of nanowires (c). SEM image of dispersed nanowires on substrate demonstrating perforation of nanowires due to the crystal pores (d).

Conclusion

Self-organization proved to be a powerful and cost-effective tool for developing a new class of semiconductor-based nanotemplates for nanofabrication. Anodic etching of semiconductor compounds under specific conditions enabled one to fabricate two-dimensional single crystals of nanopores which seemed impossible without application of lithography. Successful combination of electrochemical etching and electroplating resulted in an important technological breakthrough: nonlithographic fabrication of two-dimensional metal-dielectric periodic structures for micro-opto-electronic and photonic applications, an important prerequisite for this achievement being the elaboration of the so-called "jumping electrodeposition."

Porosification of semiconductor compounds combined with the application of special masks brought to light a variety of fascinating morphologies, including formation of networks of pores oriented parallel to the top surface of the semiconductor substrate and of porous domains excluding pore percolation between them. These findings are very important for nanofabrication. Semiconductor nanotemplates whose properties can be controlled by illumination, temperature, applied electric or magnetic fields provide more possibilities for developing hybrid nanoarchitectures by filling in the pores with other materials. In particular, no passivation or activation, leading to contamination of the porous skeleton, is required for uniform deposition along the pore's depth of metal nanotubes or nanodots.

Since the year of 2000, electrochemical etching of III-V (InP, GaAs, and GaP) compounds has been most intensively studied. Later on, II-VI compounds and GaN started to be more actively investigated and an explosion in publications devoted to porous GaN occurred over the last years. Taking into account the fascinating properties of GaN, including biocompatibility, its wide implementation in lighting technologies and high frequency/high power electronics, increasing attention should be paid in the coming years to the exploration of porosification of GaN and related nitride alloys for concrete applications.

Special attention should continue to be paid to the exploration of TiO_2 nanotube arrays finding many applications due to their high photocatalytic activity and biocompatibility. Light-driven micro-engines based on self-organized arrays of TiO_2 nanotubes, capable to pick-up, transport and release micro/nano-particles in a controlled fashion is a promising example for broadening the areas of applications of titania nanotubular structures.

Though the analysis in the present Chapter was restricted to electrochemical etching, it is not the only approach to produce porous materials. The combination of electrochemical technologies with other techniques, particularly with thermal deformation of pores and selective area sublimation, which gained momentum over the last years, could be an interesting approach for enlarging the technological tools for the preparation of nanostructured semiconductor compounds. Besides, new technological approaches have been proposed recently for the manufacture of the so-called aero-materials exhibiting a very high degree of porosity, such as aero-GaN, aero-Ga₂O₃ and aero-ZnS with broad prospects for practical applications (see Tiginyanu et al., 2019; Dragoman et al., 2019a,b; Braniste et al., 2019, 2020, 2021; Plesco et al., 2020, 2021).

Abstract

Liquid crystal systems continue to reveal new and unique manifestations of varying symmetry, dimensionality, and order in different phases. These phases serve as testing grounds for scientific concepts and predictions from theoretical considerations. This article provides an overview of the liquid crystal phases and phase transitions that have engendered significant scientific interest and investigations over the past two decades. In addition to the conventional nematic phase, general descriptions of the twist-bend, ferroelectric nematic, biaxial nematic, and blue phases are presented. Calamitic phases formed by mesogens having a molecular dipole and a chiral center, mesophases (B1-B7) arising from a bent shape of the molecular core, and discotic phases of oblate-core molecules are described.

Introduction

Liquid crystal (LC) is a state of matter intermediate between crystalline solids characterized by a regular periodic arrangement of atoms or molecules and isotropic liquids lacking any order. They exhibit varying degrees of orientational, bond orientational, and translational order in specific spatial directions. For example, molecules are arranged in stacked layers in the liquid crystal phase, known as the smectic-A (SmA) phase. It possesses one-dimensional translational order in the stacking direction, similar to a *crystal*. However, within the layers, the molecular arrangement is *liquid*-like. Such a phase that is “liquid” in two in-plane directions and “crystal” in the third direction is one example of a large number of liquid crystal phases.

Liquid crystal phases are formed by materials made of anisotropic molecules or other entities, such as nonspherical aggregates of molecules in surfactant solutions known as micelles. The simplest of the LC phases, the nematic (N) phase, is formed when the molecules are oriented on average parallel to a common direction represented by an apolar unit vector, $\mathbf{n}$, and referred to as the *director*. The structure of the phases with degrees of order higher than the N phase is different for different molecular shapes and intermolecular interactions. We will introduce different nomenclatures used to describe them. In this chapter, we shall first describe the N phase (s) and then other phases exhibited by rod-like, disk-like, and then bent-core (banana) shaped molecules. Although more than 50 LC phases are known, we will focus only on those that are of fundamental scientific interest, commonly encountered, and or have the potential for technological applications. Classification of the various phases is usually based on the concepts of symmetry (Kumar, 2000), dimensionality, and the types of order relevant to liquid crystals, such as orientational order, translational order, bond-orientational order, chirality, and dipolar ordering.

Nematic phases

In the simplest of LC phases, the nematic phase, rod-like molecules are oriented with their long axis on average parallel to the director, $\mathbf{n}$. The degree of order is described (de Gennes and Prost, 1993) by a symmetric, diagonal, traceless, and real tensor order parameter $\mathbf{Q}$:

$$\tilde{Q} = \begin{bmatrix} -\frac{S+\eta}{2} & 0 & 0 \\ 0 & -\frac{S-\eta}{2} & 0 \\ 0 & 0 & S \end{bmatrix}$$

When the scalar parameter η is zero, it describes the **uniaxial N phase**, Fig. 1, which may comprise rod-like, disk-like, or bent-core molecules. In the uniaxial N phase, orientational order exists only along $\mathbf{n}$, and the two directions orthogonal to $\mathbf{n}$ are degenerate. The parameter S then measures how well the molecules' symmetry axes are aligned. If we assume that the long axes of individual molecules make an angle θ with respect to $\mathbf{n}$, then S reduces to.

$$S = \frac{1}{2} \langle 3 \cos^2 \theta - 1 \rangle,$$

where $\langle \dots \rangle$ specifies thermal average. Optically, such phases are described by two indices of extraordinary and ordinary refraction, n_e and n_o , respectively, and the optic axis is parallel to $\mathbf{n}$.

Almost all flat-panel liquid crystal displays used in commercial products, such as laptop computers, handheld devices, and flat-panel televisions, employ the N phase. In these devices, the ability to control the spatial orientation of the optic axis of this phase with the application of an electric field permits required changes in the optical path length and the state of polarization of the transmitted light beam and forms the basis of their operation.

If the parameter η is not zero, then $\tilde{Q}$ represents a phase with additional orientational order along a secondary director, $\mathbf{m}$, in the plane orthogonal to the primary director, $\mathbf{n}$. Such a phase, shown in Fig. 2, is known as the **biaxial nematic phase**, N_{bx} phase, and it has three different indices of refraction along the three spatial directions. The parameter η measures the degree of biaxial order along the secondary director, $\mathbf{m}$.

The biaxial nematic phase was predicted (Freiser, 1970) based on symmetry arguments, followed by a flurry of activity in theoretical and experimental areas. The biaxial nematic phase was discovered (Yu and Saupe, 1980) in lyotropic liquid crystals that had remained the only type of system to exhibit this phase. However, in monomeric (or molecular) systems, there were several

Fig. 1 Schematic representation of the molecular arrangement of rod-like, discotic, and bent-core molecules (top to bottom) in the uniaxial N phase.

Fig. 2 (A) Arrangement of bent-core molecules in the N_{bx} phase. (B): X-ray diffraction patterns for the incidence directions (red and blue arrows) of X-rays with respect to the unit directions $\mathbf{n}$ and $\mathbf{m}$. Rubbed substrates we used to define $\mathbf{n}$ while an applied electric field controlled the orientation of $\mathbf{m}$.

(false) reports of its discovery. According to a group of experts who analyzed (Praefcke et al., 1998) all prior reports of the existence of the N_{bx} phase until 1998, the presence of this phase had yet to be substantiated. It is only very recently that its existence has been confirmed (Acharya et al., 2004, 2003) in the bent-core mesogens with X-ray diffraction on samples in which surface treatment and electric field were used to align the primary and secondary directors, respectively. The structure of this phase and experimental situations that confirmed the biaxiality are schematically shown in Fig. 2. After this discovery, more careful studies of the N phases formed by new bent-core materials revealed (Southern et al., 2008; Lee et al., 2009) the existence of both uniaxial and biaxial nematic phases at different temperatures in several single component systems. It should be pointed out that the results (Van Le et al., 2009) of different investigations contradicted those in Acharya et al. (Acharya et al., 2004, 2003). However, reexamination of the results in Van Le et al. (2009) using the same technique and samples revealed (Yoon et al., 2010) that differences lie in the sample and data quality and the interpretation of results in Van Le et al. (2009).

A particular case of the uniaxial N phase arises when it is constituted of chiral (lacking mirror symmetry) molecules or when a small amount of chiral agent is dissolved in the N phase. This phase, known as the **cholesteric phase**, was first observed in the cholesterol derivatives. In the cholesteric phase, the local unit vector $\mathbf{n}$ describes a helical trajectory of a well-defined pitch, Fig. 3. Since there is no directionality to the vector $\mathbf{n}$, the molecular orientation repeats after every $\frac{1}{2}$ pitch length (or π -rotation). The pitch is generally strongly temperature dependent and often comparable to the wavelength of visible light. Cholesteric phases exhibit brilliant colors due to Bragg reflection of light at the corresponding pitch. Thus, they reflect the different color of light at different temperatures. This property forms the basis of the “mood rings.” The director for the cholesteric phase, in its component form, is written as $\mathbf{n} = [\cos(q_0 z + \phi), \sin(q_0 z + \phi), 0]$.

Fig. 3 The orientation of molecules describes a helical trajectory in a cholesteric phase. Bragg reflections in the optical regime occur for wavelengths equal to $1/2$ of the pitch length.

Blue phases

Blue phases are formed by chiral compounds and appear over a very narrow temperature range between the isotropic liquid and the cholesteric phases. The term “blue phase” was coined based on their blue fog-like appearance in cholesteryl-benzoate and -nonanoate (Reinitzer, 1888; Coates and Gray, 1973). The blue phases are further classified as blue phase-I (BP-I), blue phase-II (BP-II), and blue phase-III (BP-III) based on their structure. Both BP-I and BP-II possess cubic symmetry, whereas the BP III phase is isotropic and is also known as the *amorphous* or *fog* phase. Their structures are comprised of double-twist *cylinders*, schematically shown in Fig. 4A. In a double-twist cylinder, the director rotates spatially about a radius of the cylinder (only two are shown) and becomes parallel to the cylinder axis at the center. The organization of such cylinders determines the type of BP that is obtained. For instance, when double-twist cylinders are loosely and randomly oriented in a spaghetti-like network, they form the isotropic BP-III phase (Fig. 4B). Cylinders order into a three-dimensional simple cubic structure in the BP-II phase and a body-centered cubic lattice in the BP-I phase (Fig. 4C and D). Blue phases are optically isotropic because of their cubic symmetry; however, colorful textures are usually observed due to the defects at the intersections of double-twist cylinders. Such defects self-assemble into cubic lattices and stabilize the BPs.

For a long time, the study of BPs has been limited by the very small temperature range over which they exist. However, the recent advents of wide temperature range BPs achieved via polymer stabilization or bimesogens and nanoparticle doping have engendered much research activity (Kikuchi et al., 2002; Coles and Pivnenko, 2005; Yoshida et al., 2009) involving these phases. The possibility of alignment-layer-free devices, submillisecond response, high optical contrast, wide viewing angle, and polarization-independent birefringence are some of their characteristics that are vital for their use in novel photonics and display applications.

Twist-bend nematic phase

The twist-bend nematic (N_{tb}) phase is a relatively recently discovered phase formed by achiral bent-shape molecules in which the local director traces an oblique helicoid of nanoscale pitch (Dozov, 2001; Panov et al., 2010; Chen et al., 2013, 2014; Wang et al., 2015). The local director n is tilted with respect to the helical axis $\hat{N}$ at a constant tilt angle $\theta < \pi/2$, unlike the cholesteric phase in which the tilt angle is $\pi/2$ (Fig. 5A). A negative value of the bend elastic constant is the prerequisite for the N_{tb} phase formation. One of the striking features of this phase is that it is chiral even though the constituting molecules are achiral. Consequently, the phase shows coexisting right- and left-handed helical domains (i.e., doubly degenerate chirality) (Fig. 5B). The spontaneous chirality, layer-free helical ordering with nanoscale pitch, ultrafast electro-optical response, and tunable periodic stripes are the characteristic properties of the N_{tb} phase. So far, this phase has been observed in two different systems: achiral dimeric mesogens with an odd

Fig. 4 (A) Schematic representation of a double twist cylinder (top view), wherein director can spatially rotate along a radius of the cylinder (only two are shown) and become parallel to cylinder axis at the center. The ordering of double twist cylinders in isotropic liquid leads to the formation of blue phases. The cylinders are disordered in the BPIII phase (B) but have long-range simple cubic order in the BPII phase (C), and body centered cubic order in the BPI phase (D).

number of carbon–carbon bonds in the alkyl linkage segment (e.g., two cyanobiphenyls linked with flexible heptyl chain) (Panov et al., 2010; Chen et al., 2013, 2014) and in rigid bent-core mesogens (Chen et al., 2013, 2014). Moreover, the N_{tb} phase at room temperature was recently reported in achiral rigid bent-core trimer (i.e., hybrid dimer) mesogens (Wang et al., 2015).

The unusual features of the N_{tb} phase render them very interesting for fundamental research and technological applications in fast-switching photonic devices, sensors, etc.

Ferroelectric nematic phase

The ferroelectric nematic (N_F) phase, theoretically envisioned by M. Born (Born, 1916), is a three-dimensional ordered phase possessing macroscopic spontaneous polarization density (P_s). The much-awaited experimental discovery of the N_F phase underlying the conventional N phase is very recent and is being investigated in a thermotropic calamitic mesogenic compound, namely, 4-[(4-nitrophenoxy) carbonyl] phenyl 2,4-dimethoxybenzoate (RM734) (Chen et al., 2020). These molecules possess a longitudinal dipole moment.

In the conventional N phase (Fig. 6A), the polar mesogens are oriented on average parallel to the director but antiparallel to each other, that is, in the up and down directions with equal probability eliminating the possibility of a macroscopic P_s . However, in the N_F phase (Fig. 6B), the mesogenic dipoles align nearly parallel to each other along a preferred direction with the loss of the up–down symmetry of the director orientation (i.e., $n \neq -n$). Consequently, the N_F phase develops a nonzero macroscopic polarization density, P_s , which is temperature dependent. It is predicted that highly polar and slightly wedge-shaped mesogens are essential for forming the N_F phase. The direct optical textural observation of macroscopic domains of opposite polarization in

Fig. 5 (A) Schematic of the N_{tb} phase of achiral bent shape molecule. The local director $\mathbf{n}$, helical axis $\hat{\mathbf{N}}$, and heliconical tilt θ are shown in the right-handed N_{tb} region. (B) Rope-like texture showing doubly degenerate helical structure in N_{tb} phase of achiral bent shape dimer CB7CB.

Fig. 6 Schematic representations of (A) the conventional N and (B) the ferroelectric nematic N_F phases of a thermotropic calamitic mesogen. Here, $\mathbf{n}$ denotes the director, the black and red arrows indicate the direction of the director and molecular dipoles, respectively; and $\mathbf{P}_S$ represents the spontaneous polarization density.

the absence of an external applied electric field is considered a hallmark of the N_F phase (Chen et al., 2020). Moreover, the unique characteristic features of the N_F phase, such as (i) the giant dielectric permittivity, (ii) a strong nonlinear optical response, (iii) a very fast electro-optical response (~ 100 to 1000 times faster than the conventional N phase), and (iv) having high fluidity eventually make it ideal for much anticipated advanced optical and electro-optical LC devices (Nishikawa et al., 2017; Mertelj et al., 2018; Sebastián et al., 2020; Li et al., 2021; Chen et al., 2021). Besides such exciting features of the N_F phase, specific concerns like (i) exact phase structure, (ii) structure–property relationship, (iii) nature of N- N_F phase transition, (iv) obtaining a room temperature phase with a wide temperature range, (v) direct transition to the N_F phase from the isotropic phase, and (vi) realization of the phase at room temperature essential for practical commercial devices remain to be investigated. It is worth pointing out that much has to be done to completely explore this intriguing N_F phase's fundamental and applied aspects (Larventovich, 2020).

Calamitic mesophases

Molecules with cylindrical shapes can form, in addition to the N and cholesteric phases, another class of phases that are layered structures known as the *smectic* mesophases. They all possess the translational order in the direction perpendicular to the layers.

Fig. 7 In the smectic-A phase, molecules are almost perfectly parallel to each other, $\mathbf{n}$, and the layer normal $\mathbf{z}$. Within a smectic layer, they have to particular positional or bond-orientational order.

In the two in-layer directions, the molecules also may have varying degrees of translational and bond-orientational orders to form a variety of smectic phases. These phases are denoted with a different letter in the order of their discovery.

A liquid-like order of molecules characterizes the smectic-A (SmA) phase in the directions parallel to the smectic layers. As illustrated in Fig. 7, the centers of mass of molecules lie in parallel layers, and the mass density of the phase is expected to vary in a sinusoidal manner along the z -direction. A two-component order parameter $\Psi(\mathbf{r})$ describes the SmA phase

$$\Psi(\mathbf{r}) = \Psi_0 \exp[i(\mathbf{q} \cdot \mathbf{r} + \phi)]$$

where Ψ_0 is the amplitude, ϕ is a phase factor, and the wave vector $\mathbf{q}$ is taken to be parallel to the z -direction. The molecules are oriented approximately parallel to each other within the layers, defining a director $\mathbf{n}$ that is coincident with the layer normal, $\mathbf{z}$.

The **smectic-C (SmC) phase**, Fig. 8, is very similar to the SmA phase and has layers with liquid-like molecular order. The major difference is that the molecules are tilted with respect to the layer normal. The molecular tilt, or the angle between $\mathbf{n}$ and the layer normal $\mathbf{z}$, in the SmC phase, is a strong function of temperature, as shown (Kumar, 1981) for the compound terephthal-bis-butylaniline in Fig. 9.

Other more ordered phases possess different degrees of bond-orientational and positional orders within the smectic layers. A good description of these so-called *hexatic* and *crystal* smectic phases can be found in Kumar (2000). Other exotic calamitic phases with long-range bond-orientational and positional order are known to exist with and without molecular tilt. Such phases, also known as exotic smectics, will not be discussed in this article.

Ferroelectric and antiferroelectric smectic phases are formed by molecules lacking reflection symmetry and having a permanent molecular dipole moment directed nearly perpendicular to the long molecular axis. These phases are very similar to the SmC phase with added chirality along the direction parallel to the layer normal. Molecular dipoles within a smectic layer of this phase are all oriented in the same direction, that is, in a *ferroelectric* manner. This chiral ferroelectric smectic phase is denoted as the SmC* phase (Fig. 10A); here, "*" implies the chiral nature. The SmC* phase possesses macroscopic spontaneous polarization density $\mathbf{P}$, the orientation of which can be manipulated with the help of a torque exerted on molecular dipoles by an applied electric field. Electro-optical devices based on the SmC* phase have been shown to respond with a time constant of a few microseconds, about a thousand times faster than nematic devices.

When the dipole ordering in two adjacent smectic layers is antiparallel, as shown in Fig. 10B for $E = 0$, the phase is known as the antiferroelectric SmC* phase or SmC_A* phase. The structure is still helical, but here azimuthal orientation of molecules in two layers with oppositely directed $\mathbf{P}$ describes the helical trajectory. The direction of molecular dipoles in these phases can be controlled with an applied electric field giving rise to different optical states. Two possible scenarios for the applied electric field, E , larger than a threshold field E_{th} but in applied opposite directions are also shown in Fig. 10B. Other versions of the ferroelectric phases, such as ferroelectric, are also known and can be found in the literature.

The **twist-grain boundary (TGB) phase** is an analog of the Abrikosov phase in a type-II superconductor and is made of blocks of smectic layers, with no in-plane order, permeated by regions of twist deformation, Fig. 11. Depending on the absence (or SmA) or presence (or SmC) of molecular tilt with respect to the layer normal, one obtains the TGB_A or TGB_C phases. In these phases, a twist axis exists parallel to the smectic planes. Consequently, the phase appears to be a string of smectic-like slabs of a fixed dimension

Fig. 8 In the smectic-C phase, the director $\mathbf{n}$ along which the molecules are oriented, is oblique relative to the layer normal $\mathbf{z}$. Within a layer, the arrangement of molecules is liquid-like.

Fig. 9 Temperature dependence of molecular tilt angle in the SmC and SmG phases of TBBA. The tilt continuously goes to zero as the SmA phase is approached.

l_s and arranged adjacent to each other with a narrow (of length l_d) region of twist defect. When the angle of twist, δ , between neighboring slabs is such that $2\pi/\delta$ is an integer (or a rational) number, it is referred to as the *commensurate* TGB phase, and X-ray diffraction pattern of an oriented sample features a discrete set of reflections at the same magnitude of momentum transfer vector. However, if $2\pi/\delta$ is an irrational number, then the X-ray pattern consists of a continuous diffraction ring and is referred to as the *incommensurate* TGB phase.

Discotic or columnar mesophases

Somewhat larger molecules that have nearly flat disk-like cores exhibit discotic mesophases. These molecules like to naturally pack by forming stacks (or columns) of cores, as illustrated in Fig. 12. Here, the alkyl chains are not shown for clarity. The columns of molecules form two-dimensional lattices depending on the details of molecular shape and intermolecular interactions. There is no long-range positional order in the direction of the column axis. They are *crystal* in two dimensions and *liquid* in one, in contrast to the calamitic mesophases.

Fig. 10 (A) Ferroelectric SmC^* phase; (B) Antiferroelectric SmCA^* phase in which oppositely tilted molecules describe a double helical trajectory. Red and blue arrows represent molecular dipoles. The antiferroelectric phase reverts to the ferroelectric phase when a field higher than a threshold is applied. The orientation of the molecular dipoles depends on the direction of the field.

Depending on the 2D space group corresponding to the arrangement of columns, these are given different names. In the **hexagonal (D_h) phase**, the disks are arranged in a close-packed hexagonal manner, and the plane of the molecular cores is perpendicular to the column axis. The cores can also be tilted with respect to the column axis and permit the formation of the **rectangular (D_r)** or the **rectangular face-centered** molecular arrangement. In the D_r phase, the planes of the core are tilted with respect to molecules in neighboring columns, forming a herringbone arrangement. The tilted cores are shown as ellipses in Fig. 12B.

Bent-core mesophases

As the name suggests, the bent-core (or banana) mesophases are formed by molecules resembling a boomerang (see Figs. 1 and 13). In recent years, the discovery (Niori et al., 1996; Link et al., 1997) of several novel mesophases formed by bent-core molecules has engendered much scientific interest. The phases exhibited by bent-core molecules are denoted as B_i , where $i = 1, 2, \dots, 8$, etc. The progression of the index i does not imply a systematic evolution of the structure of such phases. The structure of some of the phases has been determined while it remains uncertain for others. In the following, we will summarize what is reasonably well known at this time. We will discuss the structure of different phases in order to minimize confusion. This is an active area of research, and our understanding of some of these phases will likely undergo revision or refinements. Their names and notations are likely to change in the near future as we learn more about them and streamline the nomenclature based on symmetry.

Owing to their unique geometrical shape of molecules, the phases have revealed surprising structures and properties. For example, the formation of polar and chiral structures by *achiral* molecules is unexpected. Bent core materials show the largest electronic second-order susceptibility $\chi^{(2)}$ of all known LCs. Until now, the formation of ferroelectric phases with macroscopic electric polarization was limited to chiral molecules. Also, some bent-core mesophases exhibit interesting ferroelectric and antiferroelectric properties.

In the **B_1 phase**, the molecules partially overlap along their overall long axis, and they are arranged in smectic layers. Additionally, in a plane perpendicular to the smectic layers, molecules are organized in a 2D centered rectangular lattice, Fig. 13. Based on the studies of single domain samples, there are no indications of long-range positional correlations in the direction perpendicular to the plane containing the 2D lattice. From a symmetry point of view, this phase resembles the columnar D_r phase.

Fig. 11 Schematic drawing of TGB_A phase with pitch axis vertical. The red arrows mark the direction of the layer normal.

The unit cell dimensions, as expected, are related to the molecular size. For example, in the case of a series of bent-core azo compounds (Prasad et al., 2004), the rectangular cell dimensions were $a = 36.4 \pm 0.2 \text{ \AA}$ and $c = 30.4 \pm 0.2 \text{ \AA}$. Two forms of the B_1 phase have been reported; in one of the forms, the molecules are orthogonal to the smectic layers while in the second form, they are tilted like the SmC phase. These have been assigned the names B_{1o} and B_{1t} for the orthogonal and tilted phases, respectively.

A group of four phases that consist of stacked layers (or smectic) are known as the **B_2 phase(s)**. Here, the molecules are tilted, and the phase resembles the tilted chiral phases (SmC^* , SmC_A^*) of calamitic mesogens. The molecules forming these phases may possess a dipole moment $\mathbf{p}$ directed along their apex. Furthermore, the tilt in adjacent layers may be in the same azimuthal direction (synclinic) or opposite directions (anticlinic). The direction of molecular dipoles in one smectic layer may be parallel to that in adjacent layers (ferroelectric) or antiparallel (antiferroelectric). These four possibilities (Walba et al., 2000) are schematically shown in Fig. 14 and denoted as $SmC_A P_F$, $SmC_S P_F^*$, $SmC_S P_A$, and $SmC_A P_A^*$. It should be noted that the $SmC_S P_F^*$ and $SmC_A P_A^*$

Fig. 12 (A) Hexagonal D_h and (B) rectangular D_r columnar mesophases. Discotic mesophases lack positional order in the direction of the column axis.

Fig. 13 Molecules in the B_1 phase occupy a rectangular lattice across smectic layer interfaces—no long range-positional correlations exit in the direction perpendicular to the rectangle.

phases essentially possess the same symmetry as the calamitic ferroelectric SmC^* phase and antiferroelectric SmC_A^* phases, respectively, and they may exist in both left- and right-handed chiral states. The other two phases, $SmC_S P_A$ and $SmC_A P_F$, are antiferroelectric and ferroelectric racemates, respectively.

The B_3 and B_4 phases are crystalline phases. The B_4 phase is also called the blue crystal phase in literature. This phase is chiral and exhibits circular dichroism. Only preliminary details about the structure of the B_3 and B_4 phases are available at this time. We will not discuss the details of these phases here.

Fig. 14 (A) Different views of bent-core molecules and (B) the four structures formed in the B_2 phase. In some materials, more than one structure may be simultaneously present.

The B_6 and B_8 mesophases possess smectic stacked layer organization with no in-plane order. The B_6 and B_8 phases differ from the regular smectic phases in an important way. The smectic layer spacing is different from molecular length because, in the B_6 phase, the molecules have partial lengthwise overlap at the smectic layer interface. However, unlike the B_1 phase, there is no other order present in the B_6 and B_8 phases, Fig. 15, apart from the smectic layering. The primary layer thickness is less than the molecular length. Such phases exhibit additional peaks in X-ray diffraction patterns corresponding to a length less than twice the molecular length. A tilted analog phase of the B_6 phase has also been reported (Pelz et al., 2003). In the B_8 phase, the molecules in the neighboring layers form weak antiparallel associations with molecules in the adjacent layers and act as dimers with no overlap of the cores. The smectic layer spacing in this phase is close to twice the molecular length. The B_6 and B_8 phases can be considered analogs of the SmA_d and SmA_2 phases in the *frustrated* (or polar) smectics (Prost, 1984). The B_8 phase possesses an antiferroelectric arrangement of molecular dipoles. Tilted and chiral variants of the B_6 and B_8 phases are also likely to exist but have not yet been reported.

The B_7 phase exhibits chiral textures of both right- and left-handedness under a polarizing microscope. There are some reports of this phase responding to an applied electric field in both ferro- and antiferroelectric manner. The B_7 phase has a layered structure with either the same or different tilts in adjacent layers, which are either ferroelectric or antiferroelectric. They exhibit twisted helical filaments of high- and low-birefringence focal conics striped patterns parallel or normal to the smectic layers. Unraveling the structure of this phase has been the most challenging of all bent-core mesophases. Optical, freeze-fracture, and high-quality synchrotron x-ray diffraction studies of thin (Coleman et al., 2003) and bulk (Kang et al., 2004) samples are beginning to reveal a complex three-dimensional structure. In the B_7 phase, SmC^* -type layers are subdivided into stripes with splay deformation and defect lines shown as red and blue vertical lines in Fig. 16. Splay deformations naturally cause smectic layer (thickness) undulations because the disorder of $\mathbf{P}$ and molecular tilt produces a smaller molecular tilt and thus higher layer spacing. For a specific sign of splay, there are four possible combinations of handedness and orientations of $\mathbf{P}$ across smectic layers. These four combinations are the same as already discussed for the B_2 phase (Fig. 16). The essential features of layer undulations and molecular arrangement are illustrated in Fig. 16. The uniformity of the pitch in the layer-normal direction on a macroscopic scale requires thinner layer regions between the defect (vertical blue and red) lines to tilt and become thicker. This results in a polarization-modulated structure with a

Fig. 15 (A) Partial bilayer structure of the B_6 and (B) bilayer structure of the B_8 phase.

Fig. 16 (A) Variation of the layer spacing due to polarization modulation induced by the formation of splay stripes shown in (B). (C) Different regions separated by defect lines possess local structures similar to the SmC_5P_F and $SmCA_P F$ structures of the B_2 phase. Vectors $\mathbf{P}$ and $\mathbf{S}$ represent the spontaneous polarization density and average layer normal directions, respectively. Arrows in (B) and vector directions in (A) and (C) represent the molecular dipoles and their splay organization.

pitch much larger than the smectic layer spacing. X-ray studies reveal that the period of modulations of the smectic layers is very well-defined, giving rise to sharp Bragg peaks in the transverse direction. The undulations have a temperature and material-dependent period ranging from approximately 150 to 350 Å. The length over which the undulations are correlated is the same as the dimension over which the smectic layers prevail, that is, undulations are long-range deformations and an integral feature of the B₇ phase.

The likelihood of helical polarization-modulated filaments and twisted grain boundary (TGB) structures with polarization modulation gives rise to the possibility of forming several unique defect structures and hence the large variety of textures exhibited by the B₇ phase.

The B₅ phase (Eremin et al., 2002) is generally obtained upon cooling from the B₂ phase. Molecular arrangement in the B₅ phase is similar to the B₂ phase. The liquid-like X-ray diffraction peaks at large angles arising from the in-plane structure of the smectic layers are quite sharp. However, they remain reasonably wide to suggest that the in-plane structural order is short range. This phase is likely to be an analog of the orthogonal hexatic smectic (SmB_{hex}) phase of calamitic liquid crystals. The B₅ phase responds, albeit sluggishly, to the applied field confirming increased order and viscosity.

Many soft condensed matter systems and biological materials are liquid crystalline. For example, rod-like objects, such as tobacco mosaic virus on one hand and carbon nanotubes on the other are known to form LC phases. With our ever-expanding knowledge of naturally occurring phenomena and efforts to synthesize new molecular shapes, the list of liquid crystal phases is bound to keep growing, revealing new structures and novel scientific phenomena.

Conclusion

The field of liquid crystals is truly interdisciplinary. Organic synthesis of new molecules with different architectures has yielded new phases propelling this field in new directions. We have seen the discovery of new and unexpected phases and the phases that have been theoretically predicted. The couplings between their structure, physical properties, and responsiveness to external stimuli continue to open the doors to new opportunities for technological innovations. This trend shows no sign of slowing down, and we anticipate new research directions to arise in the coming years.

Introduction

Porous cellular metals and ceramics are now being intensively studied. This has arisen partly from a growing appreciation that biomaterials must be thoroughly understood, not only to exploit them effectively, but also to develop biomimetic materials with attractive properties and biocompatible materials and structures. Since many natural and biological materials are cellular, often with relatively high-porosity levels (although sometimes these pores are, at least, partly filled with a fluid or a soft and compliant solid in the natural state), study of manufactured porous materials has become an important branch of materials science. In fact, various types of porous materials, quite different from any biological system, are also being heavily investigated. Furthermore, certain well-established areas of porous material usage, such as filters, catalyst supports, and heat exchangers, are being subjected to renewed scrutiny, as novel porous materials and structures are developed.

Interest extends to both processing developments and to relationships between microstructure and properties. The concept of microstructure should be defined with care in highly porous materials, since it is sometimes used to refer only to the cell structure (i.e., the size, volume fraction, shape, etc. of the pores), whereas in practice, the microstructure of material constituting the cell wall may also be important. Distinctions can be drawn between different types of porous materials, based on their cell structure. The most significant classification is that between open-cell and closed-cell materials. An obvious difference is that open-cell foams are permeable to fluids, which has various implications, but there are also some rather systematic differences between the two types of materials, relating to various thermophysical and mechanical properties, and also to the applications for which they might be suitable.

However, further classification is probably needed. Some porous materials exhibit distinct, separate cells, but with some connectivity – as, for example, might result from rupturing of some cell walls. Such configurations differ noticeably from open structures having such high connectivity that it is difficult to delineate any individual cells. It might be argued that the latter should be termed “open-network materials,” rather than “cellular materials.” Open-network materials can, for example, be produced by assembling a set of fibers or fine wires. Such assemblies can be isotropic or they may be highly oriented – commonly either in-plane or uniaxially aligned – and hence exhibit pronounced anisotropy in both structures and properties. Ropes, cables, braided wires, etc. are effectively open-network materials of this type, as are various types of insulation blankets, filters, etc. There are many such products in commercial use, based on metallic, ceramic, or polymeric fibers, with or without strong interfiber bonding.

Classifying ropes, or bonded assemblies of short struts, as (open-network) materials brings into sharp focus the issue of whether such things should really be termed materials or structures. In fact, many highly porous materials should probably be treated as “quasimaterials,” since they are in many ways genuinely intermediate between the two. An important feature of quasimaterials, and of highly porous materials in general, is that the “pore architecture” introduces extra degrees of freedom into microstructural design. In thinking about terminology and classification, it is instructive to consider the combinations of pore content, connectivity, and anisotropy exhibited by various actual and putative materials and quasimaterials. This is illustrated graphically in Figure 1, which presents data for a number of well-known products and natural materials. Void content is simply evaluated, while anisotropy can be characterized via observed variations with direction of a suitable property, such as Young’s modulus E (see the section “Elastic constants and stiffness-critical lightweight structures”). Intercell connectivity is more difficult to quantify. In constructing Figure 1, the ease of permeation of fluids through the material (see the section “Fluid permeability and specific surface area”) has been used as the indicator, represented by the specific permeability κ (in m^2), which is independent of the fluid used in the measurement. Good intercell connectivity leads to high permeability. However, the permeability drops as the scale of the structure becomes finer,

Figure 1 Semiquantitative map designed to aid classification according to pore architecture, showing the combinations of void content, anisotropy, and pore connectivity exhibited by a variety of highly porous materials. ("Alulight" is a closed-cell aluminum foam made via a gas generation route.)

so κ has been multiplied by the specific surface area (in m^{-1}), which rises as this occurs, to give a connectivity parameter designed to be scale independent, at least to a first approximation. Figure 1 highlights the wide range of cell architectures obtainable. Of course, the scale of the structure is a further important variable.

Highly porous materials are also sometimes classified according to whether their cell structures are regular or stochastic (i.e., exhibiting random variations in cell size, shape, and distribution). This can affect certain characteristics, particularly mechanical properties, since it influences stress concentration effects and crack propagation paths. The distinction is not, however, a very rigid one, since porous materials which do not, strictly speaking, have regular or periodic cell structures may nevertheless exhibit a relatively narrow distribution of cell size and shape. Finally, some porous materials tend to exhibit bimodal distributions of pore size, so that, for example, the cell walls might themselves be porous. This can influence a wide range of properties. An illustration is presented in Figure 2 of cell structures in four different types of highly porous materials, exhibiting a wide range of regularity, anisotropy, connectivity, and scale.

In this article, a brief outline is given of how various properties of highly porous materials are predicted and controlled. It is sometimes possible to apply conventional composite theory, with one of the constituents taken as having zero stiffness or strength or conductivity, etc. However, models of this type often breakdown for high porosity levels, particularly as the pores become contiguous (open-celled), and, in general, rather different approaches are needed in this regime, taking proper account of the cell architecture. Furthermore, porous materials may have interesting transport properties or potential for actuation characteristics and these often require rather specialized analysis. In outlining these structure–property relationships, reference is periodically made to the applications for which particular properties are most relevant. Of course, minimization of weight is a common motivation for using porous materials, and this is a key objective for many applications, but transport properties such as permeability and

Figure 2 Microstructures of (a) a ceramic honeycomb, (b) a closed-cell metallic foam, (c) an open-cell SiOC foam, and (d) an open-network structure made by bonding metallic fibers together.

conductivity may also be of critical importance. Overall, the coverage is of necessity highly abbreviated and the bibliography provided will need to be consulted for any detailed information.

Mechanical Properties and Performance Requirements

Elastic Constants and Stiffness-Critical Lightweight Structures

The elastic constants of porous materials can be predicted using conventional composite theory models, with the “reinforcement”-ascribed zero stiffness (and zero Poisson ratio). For example, Figure 3 shows how axial and transverse Young’s modulus and Poisson ratio are predicted to vary with void content, and with void aspect ratio, according to the Eshelby method, which is based on assuming that ellipsoid-shaped inclusions (pores) are dispersed throughout the matrix. The following equation gives the elastic constants

$$C = [C_m^{-1} - f\{(C_i - C_m)[S - f(S - I)] + C_m\}^{-1}(C_i - C_m)C_m^{-1}]^{-1} \quad [1]$$

where C is the stiffness tensor, the subscripts m and i refer to matrix and inclusions (pores), S is the Eshelby tensor (dependent on inclusion aspect ratio s), I is the identity tensor and f is the volume fraction of inclusions (pores). The model is known to be unreliable for high inclusion contents, but it, nevertheless, serves to illustrate a few simple points.

First, the specific stiffness of porous materials differs little from that of the matrix, since the Young’s modulus falls off in a broadly similar way to the density (rule of mixtures line). In fact, apart from the axial stiffness of a material with aligned, highly elongated pores, which approximates closely to the rule of mixtures line, the stiffness falls off more sharply than the density, so the specific stiffness of porous materials is, in general, lower than that of corresponding monolithic materials.

Second, porous materials can be quite significantly anisotropic in stiffness, if the pores are aligned and elongated. This is the case in many natural cellular materials. In fact, it is clear from the plot that the pores do not need to be highly elongated for this to be the case, since the $s = 3$ curves are fairly close to those for infinite aspect ratio. However, it is also worth noting that the plot suggests that elastic anisotropy is unlikely to be dramatic (greater than a factor of 2 or so). Some assumptions, such as those of the equal stress model, lead to much greater predicted anisotropy, but these are known to be very unreliable, at least for cylindrical inclusions (pores). On the other hand, experimental data for transverse stiffness often suggest that it is much lower than in the axial direction. For example, typical woods (with a void content of ~ 20 – 40%) are often quoted as having an axial (parallel to grain) stiffness of

Figure 3 Predicted dependence on void content f , and void aspect ratio s , of the Young's modulus and Poisson ratio, obtained using the Eshelby method (eqn [1]).

~ 10 GPa, but a transverse value of only ~ 1 GPa. For bone, the quoted anisotropy is usually lower, but is still substantial in some cases. Partial explanation for such discrepancies is often related to difficulties in measuring a true transverse stiffness. The strength (and creep resistance) is often dramatically lower under transverse loading (see below), so that inelastic straining commonly occurs at low applied loads during stiffness measurement. However, it should also be recognized that this type of model, which takes no account of the distribution of voids, and assumes that they have no contiguity (i.e., that the cells are all closed), may be very unreliable for high-void contents and for open-cell materials. Finally, it must be noted that these models assume the base material to be isotropic. For many natural materials, such as wood, the cell walls themselves exhibit high degrees of structural alignment, and hence are highly anisotropic, both elastically and in terms of strength. Obviously, such effects should be taken into account when predicting the effect of the presence of pores.

It can also be seen in Figure 3 that the Poisson ratio may vary significantly when voids are introduced, although the relative changes are predicted to be smaller than those for stiffness. However, it should again be emphasized that, particularly at high-void contents, and with open-cell structures, geometrical aspects can assume much greater importance, and the “mean field” approach of the Eshelby method is certainly not well-suited for prediction of elastic constants at high-void contents. For highly porous materials of this type, geometrically specific models may be more appropriate. For example, consider the plots shown in Figure 4. These relate to porous materials composed of an isotropic (random) array of slender cylindrical fibers, bonded together at junction points – see Figure 2d. A model has been developed for such material, based on assuming that deformation arises solely from elastic-bending deflections of the fiber segments between junctions. The following simple equation is derived for the normalized Young's modulus

$$\frac{E}{E_m} = \frac{9(1-f)}{32(L/D)^2} \quad [2]$$

where L/D is the aspect ratio of fiber segments between joints. These stiffnesses, both measured and predicted, are well below those predicted by the Eshelby method for the void contents concerned. In general, open-cell materials are less stiff than closed-cell ones with similar void contents, while open-network materials are the least stiff. These discrepancies highlight some of the limitations of applying conventional composite theory approaches to highly porous materials, particularly if they have open-cell or open-network structures. It might also be noted that the model used to produce the plots in Figure 4 predicts a Poisson ratio value of ~ 0.32 , independent of void-content and fiber segment aspect ratio.

Finally, it should be emphasized that, while porous materials do not have superior specific stiffness to monolithic materials under uniaxial loading, they can exhibit dramatic advantages when subjected to bending moments or torques. The reason for this is that “bending stiffness” and “torsional stiffness” are raised, not only by the material having a higher Young's modulus, but also by it

Figure 4 Predicted Young's modulus of an open-network porous material comprising an isotropic array of bonded fibers, as a function of the aspect ratio L/D , of fiber segments between junctions, according to eqn [2]. Curves are plotted for several void contents (f) and some corresponding experimental data are also shown.

being located further from the neutral axis or neutral plane. Depending on the exact boundary conditions, the appropriate figure of merit for stiffness-critical weight minimization (E/ρ for uniaxial loading) is commonly $E^{1/2}/\rho$ or $E^{1/3}/\rho$ for bending, which can make highly porous materials attractive for construction of many types of stiff, lightweight structures. A simple example of this is sandwich panels, for which optimizing the design of highly porous core material is an important issue.

Strength, Fracture Mechanics, and Energy-Absorbing Structures

In general, pores are expected to cause both stress concentration effects and easier crack paths, leading to reductions in strength. In principle, a conventional fracture mechanics calculation should allow estimation of the effect of a dispersed set of (closed cell) pores on the strength and toughness. The passage of a crack through pores reduces the need for material to be fractured and hence reduces the fracture energy. Neglecting any effects of preferential crack paths or reductions in constraint near pores, the fracture energy should thus be proportional to the relative density $(1-f)$, with no dependence on pore size. The stiffness falls off with increasing void content in a broadly similar manner (see the section "Elastic constants and stiffness-critical lightweight structures"). Pores will also act as crack-initiating flaws, reducing the stress required for the onset of fast fracture. In this role, the pore size is significant. To a zeroth approximation, the strength of a porous material could thus be written as a conventional fracture mechanics strength

$$\sigma_* = \left(\frac{G_c E}{\pi c} \right)^{1/2} \approx (1-f) \left(\frac{G_{cm} E_m}{\pi R} \right)^{1/2} \quad [3]$$

where c is the flaw size, G_{cm} is the fracture energy of the base material and R is the radius of the crack-initiating (largest) pore, assumed to be spherical. This equation is plotted in Figure 5, which illustrates how high-porosity contents and large pores lead to low-fracture strengths. However, it should be recognized that experimental strengths (and fracture energies) tend to be very low for most highly porous metals and ceramics, even if the pores are relatively fine, and, in general, these predictions are over-estimates, particularly for metals. This is thought to be largely due to a tendency for cracks to preferentially follow high-porosity paths and for ductile tearing of ligaments between pores to occur readily as stress concentration effects operate. This can substantially reduce the effective toughness. While tensile strengths are higher if the pore (cell) structure is fine and regular, most experimentally measured values for highly porous materials are no higher than a few MPa, although some reported values for materials based on metal fibers are in the range of several tens of MPa.

Where highly porous materials are used in load-bearing situations, attempts are often made to ensure that they experience predominantly compressive loads (although it may be noted that this is not possible under bending and twisting moments, which is when their elastic properties can be most effectively exploited – see the section "Elastic constants and stiffness-critical lightweight

Figure 5 Predicted dependence of the fracture strength of porous metals and ceramics on void content and size, according to eqn [3].

structures"). Under uniaxial compression, highly porous materials tend to yield at relatively low stresses (from a few MPa up to a few tens of MPa) and then undergo quite large strains without the stress level rising much. This strain is associated with local plastic deformation and/or fracture and crushing events. Such deformation can be useful when substantial energy absorption is required without high stresses being generated, as in cushioning of impact events or redistribution of static or dynamic loading configurations. Of course, polymeric foams have long been used for such purposes, but they do not have high energy-absorbing potential and they also suffer from other drawbacks, such as susceptibility to fire. Metals offer particular promise in this regard, since very high local plastic strains can, in principle, be generated, due to the reduced constraint on individual cell walls or network members. This potential has not yet been fully exploited and further work is required on optimization of the energy-absorbing characteristics of highly porous metals. Some such material incorporates significant levels of ceramic in the cell walls (introduced to facilitate the processing) and this certainly impairs plasticity and energy absorption. On the other hand, there may be some situations in which predominance of brittle crushing processes over plastic deformation may be advantageous, since it will tend to result in reduced stress transfer to the component being protected.

Strength can be markedly anisotropic in porous materials. In highly aligned cellular materials, such as wood, factors of 10 between axial and transverse strengths are commonly observed. In materials such as wood and bone, this is partly attributable to the alignment of microstructural constituents (cellulose microfibrils, collagen, etc.) within the cell walls, as well as to the anisotropic cell geometry. However, even in the absence of such effects, strength anisotropy from cell or network geometry can be dramatic, with ropes providing a graphic example. The nature of the bonding in transverse directions is clearly relevant to the magnitude of the anisotropy and in some cases this can be very weak indeed.

Finally, it should be emphasized that the toughness and strength of highly porous materials is not a simple topic. While the presence of pores tends, in general, to promote premature yielding and fracture, there are situations in which the compressibility of porous materials represents a substantial advantage. For example, while the outstanding toughness and damage tolerance of wood arises partly from specific energy-absorbing mechanisms, notably fiber pullout, it is also partly due to the compressibility conferred by the presence of pores. This allows intrusive events, such as the introduction of screws, to take place without the large stress buildup and consequent macroscopic distortion or crack propagation which would tend to result with most fully dense materials, even those with relatively high toughness. Bone is also able to withstand screwing and similar fixation operations quite well, although they can sometimes cause cracking. It might also be argued that the damage tolerance and general mechanical versatility of ropes arises largely from their compressibility, or, at least, from the relative independence of individual strands, which is clearly associated with the presence of the free space. Unfortunately, most manufactured porous materials do not exhibit toughening mechanisms analogous to those operating in wood and bone, which are attributable to their complex, multiscaled microstructures. Furthermore, the damage tolerance and flexibility of rope-like materials is achieved at the cost of very high compliance and low strength in transverse directions. The degree to which most manufactured porous materials benefit mechanically from their high compressibility has thus been rather limited, although it has been noted in some cases that they are suitable for screwing etc. Nevertheless, open-network quasimaterials of various types have excellent potential for offering attractive combinations of mechanical properties and their further development seems likely.

Transport Properties and Multifunctional Applications

Electrical and Thermal Insulation Characteristics

Since there is substantial resistance to the passage of both heat and electrical charge through pores (gaseous or vacuum), porous materials have long been of interest as insulators. However, there are important differences between the two cases for porous materials. In particular, pore connectivity is often an important issue for heat flow. The main reason for this is that convective heat transfer can be significant. There is a scale effect here, since natural thermal convection within closed cells tends to be significant only when the cells are relatively large (typically, >10 mm). However, in open-cell materials natural convection can occur even with finer structures and forced convection can be an important heat transfer mechanism (to such an extent that open-pore materials are often used as heat exchangers – see the section “Fluid permeability and specific surface area”). In the electrical case, on the other hand, the focus is entirely on current paths through the matrix, assuming that the breakdown field for ionization of gas in the pores is not reached. In this section, attention is concentrated on conductive transfer.

From a mathematical point of view, conduction of heat and of electrical charge are indistinguishable. The basic equations of unidirectional heat and current flow may be written as

$$q = -K \frac{\partial T}{\partial x} \quad [4]$$

$$j = -\sigma \frac{\partial V}{\partial x} \quad [5]$$

where q is the heat flux (W m^{-2}) arising from a thermal gradient $\partial T/\partial x$ (K m^{-1}) in a material of thermal conductivity K ($\text{W m}^{-1} \text{K}^{-1}$), while j is the current density (A m^{-2}), σ is the electrical conductivity ($\Omega^{-1} \text{m}^{-1}$ or S m^{-1}) and $\partial V/\partial x$ is the electric field (V m^{-1}). It is common to use the resistivity ρ (Ωm), which is the reciprocal of the electrical conductivity. Both conductivities are proportional to the concentration of carriers, and to their mobility. For thermal conduction, either electrons or phonons can be effective carriers. Good thermal conduction is conferred by the presence of free electrons (metals) or by high phonon velocities (light, stiff materials) and large phonon mean free paths (few scattering centers, i.e., low levels of defects, grain boundaries, etc.). In contrast to this, only electrons or ions can act as carriers of electric charge. Since electrons are much more mobile than ions, materials with free electrons (metals) have vastly greater electrical conductivities than all other materials. Differences in thermal conductivity between different types of material are much less dramatic.

It therefore follows that, if the objective is electrical insulation, then most ceramics are effective anyway and there is little incentive to make them porous, unless a large volume is beneficial – for example, in increasing the thickness of a ceramic insulating layer while keeping its mass low. The electrical resistance of such a porous ceramic layer would probably be similar to a dense ceramic layer of the same thickness, although other electrical properties, such as dielectric characteristics, will often be substantially different. For metals, on the other hand, electrical conductivity will fall as the porosity is increased, but even highly porous metals are unlikely to be suitable for electrical insulation purposes. In addition, there may be interest in maximizing the electrical conductivity of porous metals, so as to facilitate electrical connections or allow resistance welding.

For thermal insulation purposes, however, there is interest in quantifying the conductivity of both ceramics and metals, as a function of porosity level and pore architecture. If the pores are treated as isolated ellipsoids, then the Eshelby method can again be employed, leading to the following equation for the conductivity (electrical or thermal)

$$K = [K_m^{-1} + f\{(K_m - K_i)[S - f(S - I)] - K_m\}^{-1}(K_i - K_m)K_m^{-1}]^{-1} \quad [6]$$

which reduces for the case of spheres to the familiar Maxwell equation

$$\frac{K}{K_m} = \frac{2(1 - f) + (K_i/K_m)(1 + 2f)}{(2 + f) + (K_i/K_m)(1 - f)} \quad [7]$$

This Eshelby expression is very similar to that for the elastic constants (eqn [1]), but these are now second-rank tensors, rather than fourth rank. Predictions from eqn [6] are shown in Figure 6a, with the void conductivity taken as zero ($K_{\text{air}} \sim 0.025 \text{ W m}^{-1} \text{K}^{-1}$, compared with typical values of ~ 10 – 200 for metals and 1 – 150 for ceramics). As with the elastic constants, the reliability is rather poor at high-void contents ($> \sim 50\%$), when the structure will not in most cases approximate well to a matrix containing a set of isolated ellipsoidal voids and the pore architecture should be taken into account. In general, conductivities fall significantly below the Eshelby-predicted levels at high-void contents, as the conduction paths through the matrix become longer and more convoluted, particularly if the pore connectivity is high. This is illustrated by Figure 6b, which presents a normalized plot of thermal conductivity data for various porous metals and ceramics, with structures ranging from a set of layered splats to open three-dimensional fibrous networks. These include the silica fiber-based space shuttle tiles and plasma-sprayed zirconia thermal barrier coatings (TBCs). The latter exhibit normalized conductivities well below the Eshelby predictions, even though the void content is relatively low. This is a consequence of their layered structure, with many poorly bonded interfaces normal to the heat flow direction. (Note that the blown metallic foams have closed-cell structures, while the infiltrated and fibrous ones are open cell.)

Figure 6 (a) Predicted dependence of the conductivity ratio on void content, f , and aspect ratio, s , obtained using the Eshelby method (eqn [6]), and (b) typical experimental ranges for the thermal conductivity ratio of various porous metallic and ceramic materials, with the Eshelby prediction for spheres included for reference purposes.

Figure 7 (a) Unit cell for a simple geometrical model of a bonded fiber array and (b) predicted resistivities compared with experimental data for two brazed materials – a mat made from long austenitic fibers ($85 \mu\Omega$ cm) and a 3D array material made from short ferritic fibers ($65 \mu\Omega$ cm).

With particular pore architectures, the behavior can often be predicted quite reliably using simple geometrical models. For example, electrical conduction through a bonded metallic-fiber array has been represented using the model shown in Figure 7a, assuming symmetry about the current flow axis, with all fibers equally inclined to it. It is easily shown that the resistivity of such material is related to that of the fibers by

$$\rho = \frac{\rho_{\text{fib}}}{(1-f) \cos^2 \theta} \quad [8]$$

where θ is the inclination angle. A comparison is presented in Figure 7b between predictions from this equation and some experimental data. The resistivity of such material tends to be much higher than that of pore-free metal, by several orders of magnitude, even when the porosity content is only $\sim 80\%$, and it can be seen that the model captures this effect. That the internal architecture is important in this case is clear from the predicted sensitivity to the fiber inclination angle.

However, it is important to recognize that such simple models are only expected to be reliable if the transport process is dominated by conventional conduction through an isotropic matrix. This is quite likely for electrical current flow through a porous metal, but for heat flow through metals or ceramics there may also be significant convective and/or radiative contributions, while

heat conduction through gas in the pores can be relevant and may be affected by pore dimensions, gas pressure, etc. Prediction of the thermal conductivity values exhibited by the materials represented in Figure 6b thus requires modeling that takes into account both structural architecture and details of the heat transfer conditions.

Fluid Permeability and Specific Surface Area

The permeability of an open-celled porous material is an important property for several types of application. Permeation of fluids through such materials is a key issue for heat exchangers, filters, fuel cells, batteries, catalyst platforms, fuel tank baffles, fluid diffusers/mixers, and various types of textiles, as well as in many natural systems such as soils and rocks. The permeation process is clearly facilitated by high cell connectivity. The scale of the structure, which can be characterized by the specific surface area

$$S = \frac{A_{\text{sur}}}{V_{\text{tot}}} \quad [9]$$

is also of importance. The resistance to fluid flow increases as the scale is refined, but a high surface area may be beneficial in some applications, including many electrochemical devices and combustion-related systems, such as solid fuel rocket propellants. For heat exchangers, there is expected to be an optimal specific surface area, allowing both rapid fluid permeation and efficient local heat exchange. This will also be true for filters, since the scale needs to be sufficiently fine to entrap the target bodies in the fluid stream, but not so fine that the entrapped bodies rapidly cause the permeability to fall as clogging occurs. Finally, it may be noted that encouragement of permeation is desirable in certain biomedical applications, such as porous surfaces of prosthetic implants into which bone growth is to be promoted. Clearly, the permeation velocities of interest may cover a very wide range. Some example materials, designed for particular applications in which permeation and surface area are relevant, are shown in Figure 8.

Figure 8 Examples of porous materials for specific applications: (a) microstructure of “Duocel” Al foam ($f \sim 90\%$), (b) rocket propellant component made of Duocel, (c) alumina filter ($f \sim 90\%$) with entrapped soot particles, and (d) plasma-sprayed zirconia thermal barrier coating (TBC), used in gas turbine engines ($f \sim 15\%$). ((c) From Green DJ and Colombo P (2003) Cellular ceramics: intriguing structures, novel properties, and innovative applications. *MRS Bulletin* 28(4): 296–300. Reproduced by permission of MRS Bulletin.)

Laminar flow of a fluid through a porous medium commonly conforms to Darcy's law, which may be written as

$$\frac{Q}{A} = \frac{\kappa}{\eta} \frac{\partial P}{\partial x} \quad [10]$$

where Q is the volumetric flow rate ($\text{m}^3 \text{s}^{-1}$), A is the sectional area (m^2), $\partial P/\partial x$ is the pressure gradient (Pa m^{-1}), η is the dynamic viscosity of the fluid (Pa s) and κ is the specific permeability (m^2). Permeability can thus be measured experimentally by recording the flow rate under a known pressure gradient. It should have the same value for all fluids.

Accurate prediction of permeability as a function of pore architecture is a relatively complex problem, but some simple models have been developed. The value of $\sqrt{\kappa}$ has dimensions of length and one approach involves equating this to some appropriate distance, such as the pore diameter or the hydraulic radius of the structure, defined as

$$R_h = \frac{f}{S} \quad [11]$$

Such a rationale leads to the so-called Kozeny equations, of which the best known is probably the Blake–Kozeny equation. This is based on semi-empirical correlations for flow through packed beds and may be written as

$$\kappa \approx \frac{f^3}{4.2 S^2} \quad [12]$$

The specific surface area S , can be measured directly or can be estimated via a suitable geometrical model for the pore architecture, giving relationships such as the following

$$S \approx \frac{3.84}{D} \quad (f \approx 0.36) \quad \text{dense random packing of solid spheres (diameter } D) \quad [13]$$

$$S = \frac{3\pi}{D(L/D)^2} \quad \left(f = 1 - \frac{3\pi}{4(L/D)^2} \right) \quad \text{cubic array of cylinders (diameter } D, \text{ length } L) \quad [14]$$

Relationships can also be derived for fiber bundles, planar random fiber arrays, woven fabrics, overlapping (poorly bonded) pancakes, etc. Predictions from the Blake–Kozeny equation, for the geometries of eqns [13] and [14], are shown in Figure 9, together with representative ranges of experimental data for various types of porous material. It can be seen that these data are, at least, broadly consistent with this simple model, with the permeability falling as the structural scale is refined, and as the void content is

Figure 9 Plot of specific permeability against the structural length scale showing predictions from the Blake–Kozeny equation (eqn [12]), for a packed bed of spheres (eqn [13]) and for a cubic array of cylindrical fibers (eqn [14]), with two different aspect ratios between the joints. Also shown are the approximate ranges of experimental data obtained with various types of porous material.

Figure 10 (a) Schematic depiction of how an isotropic porous material made by bonding of ferromagnetic fibers will tend to deform elastically in an applied magnetic field and (b) predicted (eqns [15] and [16]) and measured shape changes ($M_s = 1.6 \text{ MJ T}^{-1} \text{ m}^{-3}$; $E_f = 210 \text{ GPa}$; $B = 1 \text{ T}$).

reduced. The product of permeability and specific surface area can be taken as a measure of pore connectivity, as plotted in Figure 1, but it may be noted that all of the materials represented in Figure 9 have a relatively high connectivity.

Correlations can be established between permeability and the efficiency of convective heat transfer, but such treatments are beyond the scope of the present article. However, it is worth noting that, in practice, the choice of materials and the design of pore architecture, for applications such as heat exchangers and fuel cell elements are often driven, not solely by transport phenomena optimization, but also by mechanical performance and high temperature stability requirements.

Magnetic Actuation and Magnetomechanical Devices

Porous materials have high potential for usage in various types of actuators, partly because of their relatively low stiffness. A high permeability may also be beneficial in some circumstances – for example, it might facilitate rapid temperature change, perhaps leading to shape changes via differential thermal contraction or the shape memory effect. There is also scope for magnetic actuation with certain types of pore architecture, particularly those containing slender members of ferromagnetic materials, which tend to align with an applied magnetic field. This concept is illustrated in Figure 10a, which shows how a material composed of bonded magnetic fibers would deform in such a field. Deformation of this type has recently been analyzed. The shape changes illustrated in Figure 10a are predicted to conform to the following equations

$$\frac{\Delta Z}{Z} = \left(\frac{16 M_s B}{9 E_f} \right) \left(\frac{L}{D} \right)^2 \quad [15]$$

$$\frac{\Delta R}{R} = \left(\frac{-16 M_s B}{9 \pi E_f} \right) \left(\frac{L}{D} \right)^2 \quad [16]$$

where M_s is the saturation magnetization of the fiber material, B is the applied magnetic field, E_f is the Young's modulus of the fiber, and L/D is the aspect ratio of the fiber segments between joints. Predictions are compared with experiment in Figure 10b. It can be seen that quite substantial macroscopic strains could be generated, particularly with relatively high fiber segment aspect ratios.

Estimates have also been made of the peak strains that could be induced in this way in a surrounding matrix, such as an embryonic network of bone cells growing into the fiber array. The analysis leads to the following equation for such strains

$$\varepsilon_{\max} \approx \frac{12 \pi M_s B \sin \theta (L/D)^2}{(9 \pi E_f \tan \theta + 28 E_c (L/D)^3)} \quad [17]$$

Figure 11 Estimated dependence (eqn [17]) on fiber segment aspect ratio, of the maximum strains induced in a compliant surrounding matrix when a ferromagnetic fiber array is subjected to an applied magnetic field and (b) an integrated prosthesis design, incorporating a porous surface layer in which mechanical straining could be induced in this way ($B=1.5$ T; $M_s=1.6$ MJ T $^{-1}$ m $^{-3}$; $\theta=30^\circ$; $E_f=210$ GPa).

Predictions are shown in Figure 11a for several matrix stiffness levels. Since such a bone network would have a stiffness of the order of 0.01–0.1 GPa, and since strains of at least around 1 millistrain are known to be required for effective mechanical stimulation of bone growth, it can be seen that this model suggests that such stimulation could be generated with a suitable external magnetic field ($B \sim 1.5$ T), provided the fiber segment aspect ratio was at least ~ 5 –10. A possible prosthesis design allowing such an effect to be exploited is shown in Figure 11b.

Introduction

Dislocations are the line defects found in all crystalline materials. They are important in many branches of condensed matter physics, but most significantly they are defects, the motion of which produces plastic flow. The notion of dislocations has two starting points. First, the dislocation was introduced as an elastic singularity by considering the deformation of a body occupying a multiply connected region of space. Second, dislocations were introduced into crystal physics by Taylor, Orowan, and Polanyi in the context of analysis of the large discrepancy between the theoretical and experimental strength of crystals. These two approaches became almost immediately intertwined since the crystal dislocations are sources of long-ranged elastic stresses and strains that can be examined in the continuum framework. In fact, the bulk of the dislocation theory employs the continuum elasticity when analyzing a broad variety of dislocation phenomena encountered in plastically deforming crystals. The most comprehensive monographs devoted to the dislocation theory are books of Friedel, Nabarro, and Hirth and Lothe. An excellent simple introduction to this topic is the book by Hull and Bacon.

In this article, the crystallographic concept of dislocations is explained, the relation between dislocation movement and plastic strain is shown, the concept of the force acting on a dislocation due to externally applied stress is introduced, and the most important aspects of dislocation energetics and properties related to the long-ranged elastic fields are summarized. Then the dislocation nucleation and multiplication which is the most important ingredient in understanding of the plastic deformation, and brittle-to-ductile transition is discussed. Finally, the properties that relate to the atomic structure of materials are paid attention to; in particular, the significance of dislocation dissociation and the dislocation core structure is elucidated.

Principal Characteristics of Dislocations

A dislocation line in a continuum is obtained by cutting the material along any surface that terminates on this line, giving the two cut surfaces a relative displacement and joining them again together. Suppose the cut is made along a planar surface terminating in a straight line, and that this line and the normal to the surface define an orthonormal coordinate system. Fixed vector translations of the cut surfaces parallel, respectively, to the three axes of this system define the three basic types of dislocation. When the displacement is parallel to the line, the result is a screw dislocation. The other two translations, both perpendicular to the line, produce (equivalent) edge dislocations; if the displacement is perpendicular to the cut, a material needs to be removed or added to rejoin the two surfaces. (Three more types of “dislocation,” in which the two parts of the continuum on each side of the cut are given a relative rotation before rejoining, can be introduced. The line singularities of this type are called disclinations. These line defects play important role, for example, in liquid crystals but they are not the subjects of this article.) A straight dislocation of general mixed character is obtained when the fixed translation of the cut surfaces has components both parallel and perpendicular to the line. A curved dislocation in a plane or in three dimensions may be introduced in the same way with the surface of the cut (generally nonplanar) terminating on the curve. Since the dislocation line has been introduced as the edge of a surface, it can either terminate on external surfaces or internally by closing on itself and forming a loop. Alternatively, it may meet other dislocation lines at points where at least three dislocations meet and total sum of their Burgers vectors is zero; such points are called dislocation nodes. However, the dislocation line can never end abruptly inside the body.

The principal characteristics of a dislocation are the relative displacement of the two cut surfaces and the line terminating the cut. The former defines the Burgers vector of the dislocation and the latter the dislocation direction, the surface over which the cut has been made has no significance. In the continuum, the dislocation is defined mathematically by the relation $\oint \mathbf{u} \cdot d\mathbf{l} = \mathbf{b}$, where $\mathbf{u}$ is the displacement vector, $\mathbf{b}$ the Burgers vector, and the integral is along any circuit encompassing the dislocation line; for circuits not encircling the dislocation $\oint \mathbf{u} \cdot d\mathbf{l} = 0$. This relation is then the main boundary condition when determining within the elasticity theory, the displacement, strain, and stress fields associated with a dislocation.

Dislocations defined in the continuum have exact analogs in crystals. If the same virtual process of introducing a dislocation is employed in crystals then if the cut surfaces are to rejoin without introducing a fault along the cut, the translation vector, that is, the Burgers vector, must be a repeat vector of the Bravais lattice. A formal definition of the Burgers vector, analogous to the above path integral, invokes the concept of corresponding paths in the real crystal and a defect-free reference crystal. If a closed circuit, consisting of the same number of equivalent atoms to atom steps, is made either in the real or the reference crystal, the corresponding path in the other crystal will not, in general, be closed, and the closure failure is defined as the net Burgers vector of the dislocation lines that thread through the circuit in the real crystal.

The density of dislocations present in a body of material, ρ , is defined as the total length of dislocations per unit volume (dimension m^{-2}). The plastic strain, ϵ^{pl} , which is produced if these dislocations move, on average, a distance $-d$, is $\epsilon^{\text{pl}} = \rho b -d$, where b is the magnitude of the Burgers vector of the dislocations.

Elastic Fields and Energy Associated with Dislocations

In a continuum the dislocation defined above is a line singularity invoking a long-ranged elastic field. The details of the evaluation of the strain and stress fields in the framework of linear isotropic and anisotropic elasticity can be found, for example, in the books by Nabanna and co-workers. In the case of straight dislocations their stress and strain fields decrease as d^{-1} , where d is the distance from the dislocation line. These fields have a complex angular dependence for a fixed distance from the dislocation line. Formally, both the stress and strain diverge at the dislocation line but physically this means that there is a region, centered at the dislocation line, in which the linear elasticity does not apply. This region, the dimensions of which are of the order of the lattice spacing in crystalline materials, is called the dislocation core and it can only be fully accounted for within atomic level models of dislocations. This is discussed in more detail later in this article. The stress and strain fields of a dislocation loop decrease far away from its center as d^{-2} , similarly as the field of a dislocation dipole formed by two dislocations of opposite Burgers vectors.

The elastic energy associated with the long-range stress and strain fields of a straight dislocation is

$$E_{\text{el}}^{\text{sl}} = \frac{Kb^2}{4\pi} \ln\left(\frac{R}{r_o}\right)$$

where R is the radius of a cylinder centered on the dislocation line and r_o is the core radius. K is a constant depending on the elastic moduli and orientation of the dislocation line. (In the isotropic case, $K = [\mu/(1-\nu)](1-\nu \cos^2\theta)$ where μ is the shear modulus, ν is the Poisson ratio, and θ is the angle between the dislocation line and the Burgers vector.) This energy diverges as $R \rightarrow \infty$ and thus depends on the size of the crystal, but it is generally assumed that when a material contains many dislocations of opposite signs, their stress fields cancel at about half of the average dislocation separation and R is identified with this distance. The elastic energy of dislocation loops is always finite and depends logarithmically on their size. For example, in an elastically isotropic medium, the energy of a glissile planar circular loop of radius r (the Burgers vector lies in the plane of the loop) is

$$E_{\text{el}}^{\text{loop}} = 2\pi r \frac{\mu b^2}{4\pi(1-\nu)} \left[\ln\left(\frac{8r}{r_o}\right) - 1 \right]$$

It is noteworthy that this energy can be interpreted as the energy per unit length of the dislocation times the length of the dislocation loop $2\pi r$. This suggests that the increase of the energy of a dislocation ΔE , associated with an increase of its length Δl , can be written as $\Delta E = \tau \Delta l$, where τ is the energy of the dislocation per unit length. In general, τ will be different for different dislocation shapes, but when the curvature of the dislocation line is small, and this concept is usually restricted to this situation, τ is well approximated as the energy per unit length of a straight dislocation. It is generally dependent on the orientation of the dislocation line, but in many analyses it has been approximated by a constant of the order of $\mu b^2/2$. Since $\tau = \Delta E/\Delta l$, it also has the meaning of a line tension, in analogy with the behavior of a taut string, and this approach to evaluation of the energy change with the change in dislocation length is called the line tension approximation. (Since the energy of the dislocation depends on the angle θ between the dislocation line and its Burgers vector, a more rigorous expression for the line tension is $\tau = E + \partial^2 E/\partial \theta^2$, analogously as in the case of anisotropic surface tension. This is not essential when using isotropic elasticity when τ is always positive and $\tau \approx E$ is a good approximation. However, in highly anisotropic crystals the more rigorously determined line tension may even become negative for certain orientations. In this case, the dislocations decrease their energy by increasing their length and changing orientation. This has been observed, for example, in β -brass.)

Forces on Dislocations and Interaction between Dislocations

According to the Colonnetti principle there is no elastic interaction between internal and external stresses, that is, the response of a medium to external loading is the same whether it is self-stressed or not. However, if the source of internal stresses is displaced, the external stress may be doing work. This is what happens in the case of a dislocation. Its motion induces the relative displacement of two parts of the body by the Burgers vector within the region swept by the dislocation. One may consider an element of the dislocation line Δl that is displaced by a vector Δr in a body subject to an external stress σ_{ij}^e . The area within which the material has been displaced by the Burgers vector is $\Delta S = |\Delta r \Delta l|$ and the unit vector normal to this surface has components $n_j = \epsilon_{jlk} \Delta r_l \Delta l_k / \Delta S$

(Einstein summation convention is used). When displacing the material the external stress produced work $\Delta W = -\sigma_{ij}^e n_j b_i \Delta S = -\sigma_{ij}^e b_i \epsilon_{ijk} \Delta r_l \Delta l_k$. This can be expressed alternatively as $\Delta W = F_l \Delta r_l |\Delta l|$ with

$$F_l = \epsilon_{ijk} \sigma_{ij}^e b_i \zeta_k$$

where ζ_k is the k component of the unit vector parallel to the dislocation line. This expression can be interpreted such that F_l is the l component of the force, called the Peach–Koehler force, by which the stress σ_{ij}^e acts on the dislocation per unit length. The physical meaning of this force is that $F_l \Delta r_l$ is the work done when the dislocation of unit length is displaced by Δr , produced by the stress σ_{ij}^e that is doing work when the material is being displaced by the Burgers vector in the area swept by the dislocation. For example, in the case of an edge dislocation parallel to the axis x_3 and the Burgers vector b parallel to the axis x_1 , $F_1 = \sigma_{12}^e b$ and $F_2 = -\sigma_{11}^e b$. The component F_1 and thus the shear stress σ_{12}^e drive the glide in the slip plane $x_1 x_3$, and the component F_2 and thus the tensile stress σ_{11}^e drive the climb perpendicular to the slip plane.
